Abstract

A middle atmosphere general circulation model is used to examine the effects of zonally asymmetric ozone (ZAO) on the Northern Hemisphere planetary waveguide (PWG) during winter (December-February). The morphology of the PWG is measured by a refractive index, Eliassen-Palm flux vectors, the latitude of the subtropical zero wind line, and the latitude of the subtropical jet. ZAO causes the PWG to contract meridionally in the upper stratosphere, expand meridionally in the lower stratosphere, and expand vertically in the upper stratosphere and lower mesosphere. The ZAO-induced changes in the PWG are the result of increased upward and poleward flux of planetary wave activity into the extratropical stratosphere and lower mesosphere. These changes cause an increase in the Eliassen-Palm flux convergence at high latitudes, which produces a warmer and weaker stratospheric polar vortex and an increase in the frequency of stratospheric sudden warmings. The ability of ZAO to alter the flux of planetary wave activity into the polar vortex has important implications for accurately modeling wave-modulated and wave-driven phenomena in the middle atmosphere, including the 11-year solar cycle, stratospheric sudden warmings, and the phase of the Northern Hemisphere annular mode.

29 **1. Introduction**

30 The concept of a planetary waveguide (PWG) was first proposed by *Dickinson*
31 [1968] to describe the regions of the Northern Hemisphere (NH) winter stratosphere
32 where the background zonal wind supports the upward propagation of planetary waves.
33 *Matsuno* [1970] expanded on *Dickinson's* PWG concept and derived a refractive index
34 for planetary waves on a sphere and showed that planetary wave propagation is strongest
35 in regions where the refractive index is large and positive. For a typical NH winter zonal
36 wind distribution (Fig. 1), large, positive values of the refractive index occur in the region
37 bounded on the south by the zero wind line [*Tung*, 1979] and on the north by the southern
38 edge of the polar vortex [*Chapman and Miles*, 1981].

39 The zero wind line and the vortex edge do not, however, provide a complete
40 description of planetary wave propagation within the PWG; indeed, there exist robust
41 features of the background flow within the PWG that exert substantial control over how
42 much planetary wave activity enters the PWG from the troposphere, and where that wave
43 activity propagates once inside the stratosphere. For example, the vertical shear of the
44 zonal-mean wind near the tropopause exerts significant influence over the amount of
45 planetary wave activity that propagates upwards from the troposphere into the lower
46 stratosphere [*Chen and Robinson*, 1992]. And once planetary waves arrive in the lower
47 stratosphere, the local minimum in the refractive index associated with the negative
48 vertical and horizontal gradients of the zonal-mean wind (above and to the north of the
49 subtropical jet) splits the PWG into two 'channels' through which planetary wave activity
50 may either propagate poleward and upward into the interior of the stratosphere, or
51 equatorward where the waves are confined to the lower stratosphere [*Chapman and*

52 *Miles, 1981; Huang and Gambo, 1982; Li et al., 2006*]. For the planetary waves that
53 propagate upward and poleward into the interior of the stratosphere, the height that
54 planetary waves are able to propagate is largely controlled by the ratio of the meridional
55 gradient of potential vorticity to the zonal-mean westerly wind [*Charney and Drazin,*
56 *1961; Matsuno, 1970*]. In addition, *Nigam and Lindzen* [1989] showed that modest
57 latitudinal shifts in the location of the subtropical jet greatly alter the amount of planetary
58 wave activity that is refracted into the mid-latitude and polar stratosphere. These results
59 show that the PWG is largely defined by its meridional width (measured by the location
60 of the zero wind line), its vertical extent (measured by the refractive index), and the
61 strength of wave propagation around the subtropical jet and within the waveguide (both
62 measured by the refractive index).

63 The structures of the zonal-mean wind and PWG are determined by a balance
64 between radiative heating due to ozone, longwave radiative cooling, and dynamical
65 heating due to planetary waves. Any physical process that alters this three-way balance
66 will in turn modulate the PWG. One such process involves the feedbacks between
67 planetary wave activity and stratospheric ozone. Specifically, as planetary waves
68 propagate from the troposphere into the stratosphere during NH winter, they produce
69 large zonal asymmetries (waves) in wind, temperature, and ozone [*Gabriel et al., 2007*].
70 Observations show that zonally asymmetric ozone (ZAO) constitutes a significant
71 fraction of the total stratospheric ozone field (e.g., *Wang et al., 2005; Gabriel et al.,*
72 *2007; Crook et al., 2008*). That fraction reaches 10% during boreal winter (based on
73 decadal averages; *Crook et al., 2008*); 15% in the lower stratosphere near $\sim 70^{\circ}\text{N}$ and
74 $\sim 65^{\circ}\text{S}$ [*Gillett et al., 2009*]; 50% during the Antarctic stratospheric sudden warming of

75 2002 [Wang *et al.*, 2005]; and 50% during the breakup of the Antarctic ozone hole
76 [Crook *et al.*, 2008]. The phasing between the wind, temperature, ozone waves produce
77 fluxes that modulate both the spatial-temporal damping of the wave fields and the driving
78 of the zonal-mean circulation [Nathan and Li, 1991; Nathan and Cordero, 2007; Albers
79 and Nathan, 2012].

80 General circulation modeling studies have also shown that ZAO has a large effect
81 on the zonal-mean temperature and wind structure of the wintertime middle atmosphere
82 in both hemispheres [Kirchner and Peters, 2003; Sassi *et al.*, 2005; Gabriel *et al.*, 2007;
83 Brand *et al.*, 2008; Crook *et al.*, 2008; Waugh *et al.*, 2009; Gillett *et al.*, 2009;
84 McCormack *et al.* 2011]. For example, Crook *et al.* [2008] examined the effect of ZAO
85 on the high latitude Southern Hemisphere and found that including ZAO produces lower
86 stratosphere cooling that is comparable in magnitude to the cooling produced by the
87 springtime Antarctic ozone hole. In a study that focused on the Northern Hemisphere,
88 McCormack *et al.* [2011] carried out an ensemble of GCM simulations over the
89 December-March period and found that ZAO produces a warmer and more disturbed
90 stratospheric polar vortex and an increased incidence of stratospheric sudden warmings
91 (SSWs). Although McCormack *et al.* showed that ZAO changes temperatures and winds
92 in the polar stratosphere, the mechanisms involved in the changes were not fully
93 investigated; yet understanding the connections between ZAO and the polar stratosphere
94 is vital to producing reliable assessments of human-caused impacts on key features of the
95 climate system, including the upward flux of planetary wave activity, the frequency of
96 SSWs, and the phase of the Northern Hemisphere annular mode. Here we investigate
97 how the physics associated with ZAO changes the morphology of the PWG. The results

98 that we obtain underscore the importance of accurately accounting for ZAO in global
99 climate models.

100 In the following section we introduce the model and diagnostics that we use to
101 measure changes in the morphology of the PWG. In Section 3 we present our results, and
102 in Section 4 we discuss the implications of our results for global climate modeling.

103 **2. Model Description and Diagnostics**

104 We investigate the effects of ZAO on planetary wave propagation during NH
105 winter using the NOGAPS-ALPHA global spectral general circulation model [see, for
106 example, *Eckermann et al.*, 2009; *McCormack et al.*, 2011 and references therein].
107 NOGAPS-ALPHA extends from the surface to ~90 km in height and utilizes 68 hybrid
108 (σ -p) vertical levels with triangular truncation at wavenumber 79. The model includes
109 prognostic equations for O₃ and H₂O, which are calculated using the photochemical
110 parameterizations of *McCormack et al.* [2006, 2008]. Shortwave heating and longwave
111 cooling rates are computed using prognostic O₃ and H₂O fields and a fixed profile of
112 CO₂. Sea surface temperatures and ice distributions are specified at the model lower
113 boundary using 12-hourly observations from operational global analyses.

114 We analyze fifteen pairs of model simulations spanning early December to late
115 March (121 days). Each pair of simulations was initialized using identical profiles of
116 wind, temperature, and chemical constituents acquired from the NOGAPS-ALPHA data
117 assimilation system [*Eckermann et al.*, 2009]. The initialization dates were staggered in
118 time in order to generate an ensemble of fifteen independent pairs of model simulations
119 (for details see *McCormack et al.*, 2011). For each pair of simulations, one used fully
120 prognostic ozone in the radiative heating and cooling calculations (designated 3DO3),

121 and the other used zonal-mean values of the instantaneous prognostic ozone field to
122 evaluate the radiative heating and cooling rates (designated ZMO3). We isolate the effect
123 of ZAO on the circulation by taking the difference between 3DO3 and ZMO3 simulations
124 for any given variable. When calculated in this way, the difference between the 3DO3
125 and ZMO3 simulations isolates the effect of ZAO-heating, but not the effect of changes
126 in zonal-mean ozone heating due to wave-ozone transports. Consistent with *Albers and*
127 *Nathan* [2012], however, the heating due to the wave-ozone transports is of secondary
128 importance compared to the ZAO-heating. This means that the zonal-mean ozone
129 distribution is similar for the 3DO3 and ZMO3 simulations.

130 Statistical significance of the differences between ensemble means of model
131 variables is assessed using a Student's T-test at the 95% confidence level. As stated in
132 *McCormack et al.* [2011], the 3DO3 model runs produced four SSWs, while the ZMO3
133 runs produced only one SSW. Statistical significance calculations were also carried out
134 with all of the runs containing SSWs removed. Doing so did not change the qualitative
135 nature of our results.

136 We evaluate the morphology of the PWG in terms of two properties: (i) its shape,
137 measured by its vertical extent and meridional width; and (ii) by the strength and
138 direction of wave propagation within the waveguide itself. To measure these properties
139 we use a refractive index, Eliassen-Palm flux vectors, the latitude of the subtropical zero
140 wind line, and the latitude of the subtropical jet.

141 To diagnose the shape of the PWG and to distinguish regions of wave propagation
142 versus evanescence, we employ the spherical form of the quasigeostrophic refractive
143 index squared [*Andrews et al.*, 1987]:

$$n_s^2(\phi, z) = \frac{\bar{q}_\phi}{\bar{u}} - \left(\frac{s}{a \cos \phi} \right)^2 - \left(\frac{f}{2NH} \right)^2, \quad (1)$$

144 where

$$\bar{q}_\phi = \frac{2\Omega \cos \phi}{a} - \frac{1}{a^2} \left(\frac{\bar{u} \cos \phi}{\cos \phi} \right)_\phi - \frac{f^2}{\rho} \left(\rho \frac{\bar{u}_z}{N^2} \right)_z \quad (2)$$

145 is the zonal-mean potential vorticity gradient; \bar{u} is the zonal mean wind; ϕ is latitude, z is
 146 height, s is the spherical integer zonal wavenumber, $N(z)$ is the buoyancy frequency, f is
 147 the Coriolis parameter, H is the mean scale height [=7 km], ρ [= $\rho_0 \exp(-z/H)$] is the
 148 standard density in log-pressure coordinates, ρ_0 is the sea-level reference density, a is
 149 the radius of the Earth, Ω is the Earth's rotation frequency, and subscripts denote
 150 derivatives with respect to the given variable.

151 Planetary waves propagate in regions where $n_s^2 > 0$ and are evanescent in regions
 152 where $n_s^2 < 0$. Thus the vertical extent of the PWG is measured by the height where
 153 $n_s^2 = 0$. The meridional width of the PWG is determined by its northern and southern
 154 boundaries. We measure the northern boundary of the PWG by the latitude where n_s^2
 155 becomes negative. The southern boundary of the PWG, however, cannot be measured
 156 directly by n_s^2 . This is because $|n_s^2| \rightarrow \infty$ as $\bar{u} \rightarrow 0$, so that interpretation of n_s^2 near the
 157 subtropical zero wind line becomes problematic. What is important here is that near the
 158 zero wind line the sign of \bar{u} largely controls the sign of n_s^2 . We therefore use the
 159 location of the zero wind line as a measure of the southern boundary of the PWG,
 160 consistent with previous studies [e.g., *Holton and Tan, 1982*]. In addition, we also use the
 161 location of the subtropical jet as a diagnostic to measure wave propagation within the

162 PWG. This diagnostic is motivated by *Nigam and Lindzen* [1989] who showed that small
 163 shifts ($<3^\circ$ in latitude) in the location of the subtropical jet can greatly alter the guiding of
 164 planetary waves from the troposphere into the extratropical stratosphere.

165 When measuring changes in n_s^2 , we examine the relative importance of the
 166 strength, shear, and curvature of the zonal-mean wind. Equation (1) shows that the
 167 strength of wave propagation within the PWG depends on the ratio of the potential
 168 vorticity gradient to the zonal-mean wind, where the potential vorticity gradient (2)
 169 depends on the shear and curvature of the wind. Equation (1) also shows that as the
 170 planetary wave wavenumber s increases, n_s^2 decreases; this explains why the propagation
 171 of planetary waves into the stratosphere is largely confined to planetary wave numbers
 172 $s=1-3$ [*Charney and Drazin*, 1961].

173 We measure the strength and direction of planetary wave propagation within the
 174 PWG by using two related diagnostics: the Eliassen-Palm flux (EP-flux) and n_s^2 . For
 175 steady, slowly varying plane waves, the planetary wave group velocity is locally parallel
 176 to the EP-flux vector [*Edmon et al.*, 1980]. In addition, the EP-flux vector \vec{F} is curved up
 177 the gradient of n_s , and in particular, is guided along ridges of n_s [*Palmer*, 1981; *Palmer*,
 178 1982; *Karoly and Hoskins*, 1982]. The magnitude of the EP-flux vector \vec{F} is related to
 179 n_s^2 by [*Palmer*, 1981; *Palmer*, 1982]:

$$\|\vec{F}\| = \frac{1}{2} \exp(-z/H) \psi_s^2 n_s / (af) \quad (3)$$

180 where \vec{F} is defined in (4) and (5) below; ψ_s is the amplitude of a steady, conservative,
 181 linear wave with zonal wave number s . Regions of larger n_s^2 are associated with larger

182 EP-flux vectors and the trajectories of the EP-flux vectors are refracted up the gradient of
 183 n_s^2 . Thus the EP-flux vector and n_s^2 provide a useful way of visualizing the propagation
 184 pattern of planetary waves in the latitude-height plane. Under quasigeostrophic
 185 conditions, the EP-flux vector [$\bar{F} = (F^{(\phi)}, F^{(z)})$] and its divergence are defined in log-
 186 pressure coordinates as [Andrews *et al.*, 1987]

$$F^{(\phi)} = -\rho a \cos \phi \overline{(u'v')} \quad (4)$$

$$F^{(z)} = \rho a f \cos \phi \overline{(v'\theta')} / \theta_z \quad (5)$$

$$\nabla \cdot \bar{F} = \frac{1}{a \cos \phi} \frac{\partial}{\partial \phi} \overline{(F^{(\phi)} \cos \phi)} + \frac{\partial}{\partial z} \overline{(F^{(z)})} \quad (6)$$

187 where u and v are the zonal and meridional winds and θ is the potential temperature; the
 188 overbars and primes denote zonal-mean and perturbation quantities, respectively; and the
 189 subscripts in (5) denote partial differentiation. In accordance with (4) and (5), an upward
 190 directed EP-flux vector corresponds to a poleward heat flux; an equatorward directed EP-
 191 flux vector corresponds to a poleward momentum flux. The divergence of the EP-flux (6)
 192 measures the net planetary wave driving of the zonal-mean wind. Specifically, negative
 193 values of the EP-flux divergence (i.e. convergence) exert a westward drag on the mean
 194 wind that weakens the winter stratospheric westerly winds. When plotting the EP-flux
 195 vectors and divergence, we adopt the scaling procedure of Butchart *et al.* [1982], which
 196 ensures that the relative size of the EP-flux vector components are preserved when
 197 plotted in Cartesian coordinates. For this scaling, the vector components (4) and (5) are
 198 multiplied by $2\pi a \cos \phi$ and (4) is additionally multiplied by $c=0.0091$; the units of the
 199 rescaled EP-flux divergence are kg s^{-2} .

200 The relationship between n_s^2 and the direction and magnitude of the EP-flux has
201 been successfully used to describe a variety of stratospheric phenomenon including
202 stratospheric sudden warmings [*Butchart et al.*, 1982; *Palmer*, 1981], decadal
203 temperature and circulation trends [*Hu et al.*, 2005], annular mode variability [*Lorenz*
204 *and Hartmann*, 2002], and the propagation of planetary waves between the troposphere
205 and stratosphere [*Chen and Robinson*, 1992]. However, n_s^2 and its connection to the EP-
206 flux are built on several simplifying assumptions that may not be valid under some
207 circumstances.

208 For example, *Harnik and Lindzen* [2001] have shown that when the middle
209 stratosphere contains a reflecting surface, the traditional n_s^2 (1) may be an unreliable
210 measure of the boundaries of the PWG. This is because n_s^2 (1) is a bulk quantity that does
211 not distinguish between propagation in the meridional and vertical directions. In fact,
212 vertical propagation may be squelched while n_s^2 remains positive. This can occur when
213 meridional propagation is sufficiently strong. This point was underscored by *Harnik and*
214 *Lindzen* who defined a wavenumber diagnostic, which, together with a linear model,
215 provided boundaries for meridional and vertical wave propagation. Using the diagnostic
216 for specific cases during Southern Hemisphere winter, they found that when a reflecting
217 surface formed in the upper stratosphere, it was about 10 km lower than that produced by
218 the traditional n_s^2 .

219 Because the differences between the *Harnik and Lindzen* [2001] wavenumber
220 diagnostic and the traditional n_s^2 diagnostic appear to be largest when reflecting surfaces
221 form in the upper stratosphere, we calculated a reflection index following *Perlwitz and*

222 *Harnik* [2003] for all of our 3DO3 and ZMO3 model simulations. We found that for the
223 3DO3 ensemble simulations, 6 out of 15 Januarys had reflective surfaces in the upper
224 stratosphere. For the ZMO3 simulations, only 3 out of 15 winters had reflective surfaces
225 (one in December and two in January). For the February simulations there were no
226 reflective surfaces in the upper stratosphere. For this reason, and since February is also
227 the time when our simulations show that ZAO has its strongest effect on the model
228 circulation (see Section 3), we can expect n_s^2 to be a representative measure of the
229 morphology of the planetary wave guide.

230 Another potential concern regarding the diagnosis of wave propagation using (1)-
231 (6) is that the mathematical relationship between the EP-flux and n_s^2 formally holds for
232 slowly varying plane waves and for sufficiently small wave damping. These conditions
233 may not be met in the real atmosphere due to wave reflection, tunneling, or damping,
234 which may complicate the interpretation of the n_s^2 /EP-flux relationship or invalidate it
235 altogether [*Harnik* 2002].

236 The above caveats notwithstanding, our results will show that the relationship
237 between the EP-flux divergence and n_s^2 explains a significant portion of the wind and
238 PWG variability observed in the model simulations that include ZAO.

239 **3. Results**

240 We compare the morphology of the PWG for the ZMO3 and 3DO3 cases for the
241 winter months of December, January, and February (DJF). We follow with a discussion
242 describing how ZAO causes the morphology of the PWG to evolve differently during
243 January and February.

244 **3.1. Mean Winter Results (December-January-February)**

245 Figures 1 and 2 show, respectively, the ZMO3 and 3DO3 ensemble mean zonal-
246 mean wind and n_s^2 for stationary planetary wave $s=1$ averaged over DJF; similar results
247 were obtained for planetary wave $s=2$ (not shown). Figures 1 and 2 show features of n_s^2
248 that are common to previous studies of NH planetary wave propagation (*Chapman and*
249 *Miles*, 1981; *Chen and Robinson*, 1992). These features include a local minimum in n_s^2 in
250 the middle latitude lower stratosphere ($\sim 42^\circ\text{N}$ latitude at 20 km) and a local maximum in
251 n_s^2 between $50^\circ\text{-}60^\circ\text{N}$ latitude and 25-30 km. The local minimum in n_s^2 is due to the
252 large negative gradient in potential vorticity (2). The large potential vorticity gradient
253 results from the negative vertical and meridional gradients in zonal-mean wind located
254 just above and to the north of the subtropical jet (Figure 1a). For waves originating in the
255 extratropical troposphere, the local minimum in n_s^2 in the lower stratosphere splits the
256 vertical propagation of planetary waves along two ‘channels’ [*Chapman and Miles*, 1981;
257 *Huang and Gambo*, 1982; *Li et al.*, 2006]. The splitting of wave propagation along two
258 wave channels is a common feature of the NH PWG during the mid- to late winter (the
259 time period of interest in this study), but may be less common during the early winter
260 months of November-December (compare Figure 9 bottom left and bottom right of *Shaw*
261 *et al.*, 2010). We shall refer to the two channels as the southern and northern wave
262 channels.

263 Along the southern channel of the PWG, the planetary waves are confined to the
264 lower to middle stratosphere where they are refracted equatorward, eventually dissipating
265 before they reach the upper stratosphere. Along the northern channel, the waves
266 propagate through the local maximum in n_s^2 associated with the weak westerly winds

267 located slightly north of the region between the subtropical and polar night jets. The
268 region between the jets is centered at $\sim 56^\circ\text{N}$ latitude and 25 km in Figure 1a. From the
269 local maximum in n_s^2 , waves tend to propagate upwards along the southern edge of the
270 vertical axis of the polar night jet, where wave propagation is enhanced due to the
271 combination of positive vertical and meridional shear of the zonal-mean wind. Waves
272 that emanate from the sub-polar and polar regions tend to merge into the guide formed by
273 the northern channel. The EP-flux vectors shown in Figures 1b and 2b clearly show
274 planetary wave propagation along these two channels.

275 Planetary wave activity within the PWG is generally strongest during mid- to late
276 winter, when the polar vortex is generally weaker. This is consistent with *Charney and*
277 *Drazin* [1961] who showed that planetary wave propagation from the troposphere into the
278 stratosphere is favored in westerly flows that are not too strong. Because NH zonal
279 asymmetries in ozone are predominantly generated by planetary wave activity, we also
280 expect the ZAO field to be largest in late winter [*Peters and Entzian*, 1999; *Peters et al.*,
281 2008]. As winter wanes, the solar zenith angle decreases and the ozone heating becomes
282 stronger. Thus we can anticipate that the effects of ZAO, particularly with regard to the
283 PWG, will be strongest in mid- to late winter. This is indeed the case, and in the
284 discussion that follows, we focus our attention on January and February.

285 *McCormack et al.* [2011], in a preliminary study examining the effects of ZAO on
286 the NH wintertime circulation, found that ZAO has the largest affect on the dynamics of
287 the NH polar winter stratosphere during January and February. Figures 3a and 3b show
288 the difference in the ensemble mean zonal-mean wind (3DO3 minus ZMO3) for January
289 and February. Wind differences that are statistically significant above the 95%

290 confidence level are shaded. Overall, the effects of ZAO produce weaker westerly flow.
291 During January (Fig. 3a), the largest ensemble mean differences (~ 10 m/s) are located
292 throughout the tropical stratopause region. During February (Fig. 3b), the zonal wind
293 differences extend poleward and downward with the largest differences (~ 17 m/s) located
294 in the polar region between 40-50 km. Although the largest change in the wind speed
295 occurs in February in the NH, changes in n_s^2 and the EP-flux divergence begin in January
296 and grow as the winter season proceeds. By February there is a large change in wind
297 speed in the extratropical stratosphere. We next consider January and February in more
298 detail.

299 **3.2. January Results**

300 Figures 4a and 4b show the 3DO3 EP-flux divergence and EP-flux difference
301 (3DO3 minus ZMO3) contours for January. Also shown are the corresponding EP-flux
302 vectors. Figure 4b shows two important changes in the EP-flux due to ZAO. First,
303 between 10-15 km and $\sim 10^\circ$ - 50° N latitude, the EP-flux difference vectors are directed
304 poleward. This corresponds to an increase in equatorward momentum flux, which is
305 associated with the weakened extratropical upper tropospheric and lower stratospheric
306 westerly flow. Second, between 10-30 km and $\sim 50^\circ$ - 80° N latitude, the EP-flux difference
307 vectors are directed upwards. This represents an increase in both vertical wave
308 propagation and the meridional heat flux, which is associated with the weakening of the
309 westerly flow. The change in the momentum flux in January continues to grow as the
310 winter proceeds and will be important for explaining the equatorward shift in the
311 subtropical jet seen later in February (Figure 3b). The effect of the increased meridional
312 heat flux on the PWG, however, becomes readily apparent by the end of January.

313 ZAO affects the zonal-mean wind, and by extension n_s^2 , via two pathways [*Albers*
314 *and Nathan, 2012*]. Along the first pathway, ozone-flux convergences due to ZAO
315 modify the zonal-mean ozone field. The change to the zonal-mean ozone field produces
316 changes in the zonal-mean radiative heating rate and thus the zonal-mean temperature. To
317 maintain thermal wind balance, the changes to the zonal-mean temperature result in
318 changes to the zonal-mean wind. Along the second pathway, ZAO-heating affects the EP-
319 flux divergence, which in turn also modulates the zonal-mean wind. However, the
320 difference between the 3DO3 and ZMO3 zonal-mean ozone fields is small between
321 December and mid-February, which means that the first pathway plays a minor role in
322 driving the changes to n_s^2 in the 3DO3 simulations. As a result, any changes in the zonal-
323 mean wind and n_s^2 during this time period must be due to changes in the EP-flux
324 divergence associated with ZAO-heating.

325 Figure 4b shows that the increase in the EP-flux divergence within the northern
326 channel of the PWG is primarily due to an increase in the vertical component of the EP-
327 flux vector (this is confirmed by the near verticality of the EP-flux difference vectors in
328 this region). To confirm that changes in the meridional heat flux precede changes in n_s^2
329 within the northern channel of the PWG, we next compare the time evolution of the
330 meridional heat flux and n_s^2 .

331 Figure 5 shows the time series of the ensemble mean and area weighted average
332 of the meridional heat flux and n_s^2 . The time series spans December 1 to February 28 and
333 the area weighted average is between 50°-75°N at ~27 km in height. This height and
334 latitude band lies roughly in the center of the northern channel of the PWG. During the

335 time period considered, the heat flux and n_s^2 exhibit qualitatively different behaviors
 336 before and after January 5.

337 Prior to January 5, the difference between the 3DO3 and ZMO3 heat fluxes
 338 (Figure 5a) does not produce a significance difference in the respective values of n_s^2
 339 (Figure 5b). In contrast, after January 5, the heat flux of 3DO3 remains larger than the
 340 heat flux of ZMO3 (the exception is a small two-day period just after Jan. 10). As a
 341 result, n_s^2 for the 3DO3 ensembles also become larger than n_s^2 for the ZMO3 ensembles
 342 during mid- to late-January. Yet there are two important differences between the
 343 temporal evolution of the n_s^2 versus the heat flux. First, the increase in the 3DO3 n_s^2 lags
 344 the increase in the 3DO3 heat flux by ~ 5 days. Second, the increase in the 3DO3 n_s^2
 345 remains rather small until the final 5-10 days of January. The time lag between the
 346 change in the heat flux and the change in n_s^2 is not unexpected because it takes time for
 347 the ZAO-induced changes in the planetary waves to be manifest as changes in the zonal-
 348 mean wind. Once the ZAO-heating triggers the initial increase in the meridional heat
 349 flux, however, a positive feedback cycle is initiated that ultimately affects the PWG and
 350 any subsequent planetary wave activity. In short, the initial increase in the EP-flux
 351 convergence due to ZAO-heating causes changes in the strength of the extratropical
 352 westerly flow and the meridional potential vorticity gradient that combine to increase n_s^2 .
 353 The increase in n_s^2 , in turn, causes a further increase in vertical wave propagation that
 354 reinforces the initial increase in the EP-flux convergence. To gain further insight into the
 355 increase in vertical wave propagation, we next consider the spatial evolution of the
 356 vertical component of the EP-flux ($F^{(z)}$) and the PWG.

357 Figure 6a shows contours of the January ensemble mean difference (3DO3 minus
 358 ZMO3) in $F^{(z)}$ (5). The increase in $F^{(z)}$ is primarily concentrated in two plumes located
 359 within the northern and southern wave channels. The primary plume originates in the
 360 sub-polar and polar latitudes centered at $\sim 60^\circ\text{N}$ latitude, while the second, smaller plume
 361 is centered at $\sim 30^\circ\text{N}$ latitude. The two plumes and the gap between them are
 362 representative of three features of the PWG discussed in Section 3.1; that is, the plumes
 363 represent an increase in vertical wave propagation along both the northern and southern
 364 planetary wave channels, while the gap between the plumes of $F^{(z)}$ is likely due to the
 365 local minimum in n_s^2 seen in Figures 1b and 2b at $\sim 42^\circ\text{N}$ latitude and 20 km.

366 To examine the connection between the increase in $F^{(z)}$ along each of the
 367 planetary wave channels and changes in the morphology of the PWG, we computed the
 368 change in n_s^2 (3DO3 minus ZMO3) for two periods during January. Guided by the n_s^2
 369 time series in Figure 5, we calculated the change in n_s^2 between January 1-25 and January
 370 25-31. Between January 1-25, there is very little change in n_s^2 (not shown); this result is
 371 consistent with the relatively small change in the January monthly mean zonal-mean
 372 wind shown in Figure 3a and the n_s^2 time series shown in Figure 5b. The final 5 days of
 373 January, however, show changes in n_s^2 that match very well with the increase in vertical
 374 wave propagation. In particular, the two plumes in $F^{(z)}$ shown in Figure 6a are
 375 collocated with notable increases in n_s^2 along both planetary wave channels (Figure 6b).

376 We next examine how the ZAO-related changes in the PWG that first appear in
 377 late January expand and amplify to produce the large change in the zonal wind in
 378 February.

379 **3.3. February Results**

380 Figure 3b shows that ZAO produces statistically significant decreases in the
381 zonal-mean westerly flow of $5\text{-}11\text{ ms}^{-1}$ in the equatorial upper stratosphere and middle
382 mesosphere, as well as decreases of $3\text{-}18\text{ ms}^{-1}$ throughout the NH extratropical
383 stratosphere and mesosphere during February. A third, smaller region of statistically
384 significant wind difference is located near the location of the subtropical jet at $\sim 30^\circ\text{N}$ in
385 the upper troposphere and lower stratosphere (UTLS); the wind change at this location
386 represents an increase of $\sim 1\text{-}3\text{ ms}^{-1}$. The differences in the NH zonal-mean wind show
387 three notable results. First, the decrease in the wind speed in the tropical upper
388 stratosphere and lower mesosphere causes a northward migration of the tropical easterlies
389 and a northward shift of the zero wind line. As Figure 7 shows, the northward shift in the
390 zero wind line varies from about 1° to 8° latitude between about 30 km and 65 km in
391 height. Second, the decrease in wind speed within the extratropics and polar region
392 represents a weaker polar vortex and a warmer stratosphere (see also *McCormack et al.*
393 [2011], their Figure 2). Third, the increased wind speed in the subtropical UTLS shifts
394 the subtropical jet equatorward by about 3° . The zonal wind differences in Figure 3 and
395 Figure 7 qualitatively agree with recent studies suggesting a connection between
396 northward shifts in the upper stratospheric zero wind line and an increase in the
397 frequency of SSWs. For example, *Gray* [2003] found that similar to the so-called
398 ‘Holton-Tan’ mechanism in the lower stratosphere [*Holton and Tan*, 1982], a northward
399 shift in the upper stratospheric zero wind line produces a narrower PWG that directs more
400 planetary wave activity poleward. The increase in planetary wave activity induces more
401 wave drag on the zonal-mean circulation and creates a warmer extratropical and polar

402 stratosphere and an increased incidence of SSWs. Indeed, as our EP-flux diagnostics will
 403 show, the combination of a narrower PWG and an increase in wave propagation combine
 404 to produce an increase in wave drag, the weaker polar vortex shown in Figures 1a and 2a,
 405 and an increased incidence of major SSWs (four in the 3DO3 ensembles versus one in the
 406 ZMO3 ensembles).

407 Figures 8a and 8b compare values of the February ensemble mean n_s^2 (1) for
 408 ZMO3 and 3DO3 for stationary planetary wave $s=1$. The n_s^2 scale varies from red to
 409 blue, which corresponds with large to small n_s^2 , respectively. Regions where planetary
 410 waves are evanescent ($n_s^2 < 0$) are denoted by white space. In addition to showing n_s^2 ,
 411 Figures 8a and 8b are overlaid with a qualitative outline of the PWG where values at
 412 either extreme of the n_s^2 scale are excluded and shaded by the transparent light grey
 413 color; the solid black line that outlines the PWG traces the 15 and 65 n_s^2 contours on the
 414 poleward and equatorward side of the PWG, respectively. Outlining the PWG this way
 415 greatly aids in visualizing changes to n_s^2 ; moreover, excluding the extreme values of n_s^2
 416 is a physically reasonable approximation for two reasons. First, approaching the
 417 subtropical zero wind line, $n_s^2 \rightarrow \infty$ as $\bar{u} \rightarrow 0$. In this limit, n_s^2 becomes an unreliable
 418 measure of wave propagation. Second, because planetary waves tend to propagate
 419 towards and through large values of n_s^2 , changes in n_s^2 within the region of very small n_s^2
 420 on the poleward side of the PWG play a minor role in determining where planetary waves
 421 propagate. Regardless, choosing different extreme values to exclude from the PWG
 422 outline does not change the qualitative nature of our results.

423 Figure 8 shows that ZAO increases planetary wave propagation in three important
 424 ways. First, the vertical extent of the PWG increases, which allows the waves to
 425 propagate 10 to 15 km higher within the mesosphere between 45°-70°N. Second, ZAO
 426 causes an increase in the magnitude of n_s^2 throughout the entire stratosphere, and in
 427 particular, an increase in wave propagation along both the southern and northern wave
 428 channels. The increase in n_s^2 along the southern wave channel is significant beginning at
 429 the surface and extending upwards to ~35 km between 30°-40°N. The increase in n_s^2
 430 within the northern wave channel extends upwards from ~20 km all the way to into the
 431 mesosphere near ~75 km. And third, ZAO also causes a significant increase in n_s^2 in the
 432 polar UTLS between ~60°-80°N. The increases in wave propagation described above are
 433 each due to different structural changes in the wind and are embodied by competing
 434 terms in n_s^2 (1), namely, the strength of the zonal mean wind versus the meridional
 435 potential vorticity gradient.

436 According to the first term on the RHS of (1), weaker westerly winds and
 437 increases in the meridional potential vorticity gradient together increase n_s^2 . Ozone-
 438 induced changes in the potential vorticity gradient, in turn, are due to changes in the
 439 meridional and vertical shear terms of the zonal-mean wind [the second and third terms
 440 on the RHS of (2)]. We compared each of the terms in (2) for the 3DO3 and ZMO3 sets
 441 of ensembles and found that nearly all of the changes in n_s^2 due to changes in the
 442 potential vorticity gradient are due to the third term on the RHS of (2). Further details can
 443 then be exposed by expanding the third term on the RHS of (2), which yields

$$-\frac{f^2}{\rho_s} \left(\rho_s \frac{\bar{u}_z}{N^2} \right)_z = \left(\frac{f^2}{HN^2} + \frac{f^2}{N^4} \frac{dN^2}{dz} \right) \bar{u}_z - \frac{f^2}{N^2} \bar{u}_{zz}. \quad (7)$$

444 The first term on the RHS of (7) is proportional to the vertical shear of the mean wind,
 445 while the second term is proportional to the vertical curvature of the mean wind. Thus an
 446 increase in positive vertical wind shear (or a decrease in negative vertical wind shear)
 447 increases the meridional potential vorticity gradient (2) and increases n_s^2 (1). Based on a
 448 numerical comparison of the two terms on the RHS of (7), we found that the vertical
 449 shear term is the dominant term and largely accounts for changes between the 3DO3 and
 450 ZMO3 ensembles. Thus the changes in n_s^2 shown in Figure 8 can be explained by the
 451 ratio \bar{u}_z / \bar{u} .

452 With the exception of the UTLS region along the southern wave channel, the
 453 entire extratropical stratosphere and lower mesosphere is characterized by weakened
 454 westerly winds (Figure 3b), consistent with an increase in n_s^2 within the PWG shown in
 455 Figure 8. The weakened polar vortex in the 3DO3 simulations, however, also affects the
 456 vertical wind shear. Figure 2a shows that the location of the maximum wind speed in the
 457 vortex core extends from ~60 km at ~40°N to ~40 km at ~60°N, so that much of the
 458 region above ~40-50 km is characterized by negative vertical wind shear, while the
 459 region below ~40 km is largely characterized by positive vertical wind shear. These
 460 features are clearly seen in Figure 9a, which depicts the change in the vertical wind shear
 461 between the 3DO3 and ZMO3 ensembles. As a consequence of the weaker polar vortex
 462 in the 3DO3 simulations, the vertical wind shear along the upper portion of the northern
 463 wave channel (between 40°-70°N and above ~40 km) and along the southern wave
 464 channel (between 30°-40°N in the UTLS) becomes weaker (less negative); this

465 contributes positively to the increase in n_s^2 . In contrast, the region along the lower portion
466 of the northern wave channel (between $\sim 55^\circ$ - 85° N and 10-40 km) is characterized by a
467 decrease in positive vertical wind shear that contributes negatively to n_s^2 ; thus the
468 increase in n_s^2 in the this region is due solely to the weakened westerly winds in the
469 3DO3 simulations. Each of the changes in the magnitude and vertical shear of the zonal-
470 mean wind just described will prove to be important for explaining the increases in the
471 February EP-flux convergence as discussed in the next section.

472 **3.4. Discussion**

473 We have shown that ZAO-heating causes an increase in the EP-flux beginning in
474 early to mid-January. This initial increase in the EP-flux produces changes in the zonal-
475 mean wind that are manifest as changes in the PWG. The changes in the PWG occur via
476 variations in the location of the subtropical jet, shifts in the latitude of the subtropical
477 zero wind line, and the strength of wave propagation within the extratropical stratosphere.
478 These changes in the EP-flux and PWG represent a positive feedback, where the initial
479 ZAO-induced changes in wave amplification/damping trigger changes in the PWG that
480 affect subsequent planetary wave activity entering the stratosphere. As the winter season
481 progresses the ZAO-induced changes in the PWG become increasingly important.

482 To better understand how ZAO affects the PWG during late January and
483 February, we consider how the ZAO-weakened lower stratospheric zonal winds combine
484 with the equatorward shift in the subtropical jet. First some background.

485 Using a primitive equation model, *Nigam and Lindzen* [1989] found that small
486 perturbations ($< 5 \text{ ms}^{-1}$) to the zonal-mean wind could produce equatorward shifts in the
487 location of the subtropical jet. Although small, these shifts could nonetheless

488 substantially enhance the guiding of planetary waves from their primary source region
489 (the Himalayas at $\sim 27^\circ\text{N}$) into the polar stratosphere. Similarly, *Hu and Tung* [2002]
490 showed that the low index phase of the Northern Hemispheric annular mode (which is
491 characterized by an equatorward shift in the NH zonal jet), is associated with weakened
492 zonal-mean winds and increased n_s^2 in the UTLS region between $60^\circ\text{-}80^\circ\text{N}$. In addition
493 to changes in n_s^2 , *Limpasuvan and Hartmann* [2000] showed that the low index phase of
494 the Northern annular mode is also characterized by anomalous increases in poleward
495 directed EP-flux vectors; the resulting increase in equatorward momentum fluxes are
496 associated with a weakened stratospheric westerly winds. Our results suggest that ZAO
497 modulates n_s^2 and the EP-flux in a similar fashion to each of the phenomenon described
498 by *Nigam and Lindzen*, *Hu and Tung*, and *Limpasuvan and Hartmann*. Indeed, the
499 equatorward shift in the subtropical jet in the 3DO3 simulations is accompanied by: an
500 anomalous increase in upward directed EP-flux vectors into the stratosphere and an
501 anomalous increase in poleward directed EP-flux vectors in the UTLS between $\sim 30^\circ\text{-}$
502 75°N (Figure 9b); weakened westerly winds (Figure 3b); and increased n_s^2 values (Figure
503 8b) throughout the extratropical UTLS. The increase in the anomalous poleward and
504 upward directed EP-flux vectors observed in February reinforce the positive feedback
505 cycle between the EP-flux convergence and n_s^2 first established in late January; the net
506 result is an increase in wave propagation throughout both channels of the PWG. To better
507 understand the implications of the expansion of the PWG in the vertical and the increase
508 in wave propagation within the PWG, we next consider the EP-flux convergence.

509 Figures 10a shows contours of the difference (3DO3 minus ZMO3) of the EP-flux
510 convergence in February. In a continuation of the EP-flux convergence differences that

511 first appeared in January, the February difference clearly shows two plumes of increased
512 convergence along both the northern and southern wave channels. There is a 30-50%
513 increase in the EP-flux convergence along the northern wave channel between 15-20 km,
514 and a 15-100% increase along the southern wave channel at the same heights. As in
515 January, the two plumes of increased EP-flux convergence correspond with significant
516 increases in vertical wave propagation; this can be verified by examining the increased
517 EP-flux vectors in Figure 9b and more specifically, the increase in $F^{(z)}$ shown in Figure
518 10b. In addition to an increase in magnitude, the ZAO-induced increase in $F^{(z)}$ during
519 February also extends ~10-15 km higher than was observed during January (compare
520 Figures 6a and 10b); this is consistent with the 10-15 km increase in height of the
521 February PWG depicted in Figure 8.

522 The increases in vertical wave propagation along the northern and southern wave
523 channels, however, correspond to the qualitatively different changes in wind structure
524 described in Section 3.3. The increase in vertical wave propagation along the southern
525 wave channel (~30°-40°N) in the UTLS is due to a combination of changes in the vertical
526 shear, meridional shear, and curvature of the zonal-mean wind rather than changes in the
527 magnitude of the wind. This is verified in Figure 3b, which shows that the UTLS is
528 characterized by an increase in the mean wind that contributes negatively to the
529 magnitude of n_s^2 . The dominant contribution to the increase in n_s^2 and the increased
530 vertical propagation along the southern wave channel is due to the increase in positive
531 vertical wind shear depicted in Figure 9a between ~30°-40°N. The meridional shear and
532 curvature terms (not shown) also contribute to the increase in n_s^2 , but their contribution is
533 secondary to that of the vertical shear term. The importance of vertical wind shear along

534 the tropopause is perhaps not surprising in light of the study by *Chen and Robinson*
535 [1992] who showed that even small changes in vertical wind shear near the tropopause
536 may produce significant changes (20-40%) in n_s^2 and EP-flux convergence in the UTLS.
537 In contrast to the changes along the southern wave channel, the increase in vertical wave
538 propagation along the northern wave channel are due to increases in n_s^2 associated solely
539 with the weakened westerly winds; this is verified by noting the decrease in positive
540 vertical wind shear (Figure 9a) that contributes negatively to n_s^2 .

541 Despite the similarities between the distributions in the January and February EP-
542 flux convergences (compare Figs. 4b and 10a), there are two notable changes between the
543 two months. First, the local minimum in the EP-flux convergence along the northern
544 wave channel (centered at $\sim 60^\circ\text{N}$ and 18 km) has increased slightly from -36 to -32 kg s^{-2} ,
545 while the local minimum along the southern wave channel (centered at $\sim 32^\circ\text{N}$ and 16
546 km) has decreased by $\sim 60\%$ from -27 to -43 kg s^{-2} . This indicates that the local increase
547 in n_s^2 and the equatorward shift in the subtropical jet have combined to significantly
548 increase the poleward and vertical propagation of planetary waves (Figure 9b and 10b),
549 which results in the large increase in the EP-flux convergence along the southern wave
550 channel. Second, while the increased EP-flux convergence due to ZAO extended all the
551 way from the middle stratosphere down to the surface between $50^\circ\text{-}70^\circ\text{N}$ during January
552 (Figure 4b), there is no increase in convergence between $\sim 10\text{-}15$ km and $30^\circ\text{-}70^\circ\text{N}$ during
553 February (Figure 10a); this difference cannot be explained by the changes in n_s^2
554 described earlier. There are several possible explanations for this apparent discrepancy
555 between the increase in the EP-flux convergence and n_s^2 .

556 One possible explanation for the increase in the EP-flux convergence in the UTLS
557 is associated with the ability of ZAO to alter the EP-flux convergence through wave
558 amplification/damping. Indeed it is ZAO-heating that triggers the initial increase in the
559 EP-flux convergence and the PWG in mid- to late-January described in Section 3.2. The
560 ozone-modified refractive index derived in *Nathan and Cordero* [2007] describes how
561 ZAO and zonal-mean ozone combine to alter both planetary wave propagation and wave
562 damping. *Albers and Nathan* [2012] subsequently used the ozone-modified refractive
563 index to show how changes in wave propagation and damping due to ZAO act together or
564 in opposition to produce small or large changes in the EP-flux in the lower stratosphere.
565 Although the current experimental setup does not make it possible to separate ZAO-
566 related effects due to wave propagation and wave damping, it is indeed possible that the
567 apparent discrepancy between the increase in n_s^2 seen in Figure 8 and decrease in the EP-
568 flux convergence seen between ~5-15 km and 30°-70°N in Figure 10 could be related to
569 ZAO-induced changes in wave damping and wave propagation that are not taken into
570 account by the inviscid form of n_s^2 (1) employed in this study. This issue will be the
571 subject of future modeling and observational studies.

572 A second possible explanation for the apparent discrepancy between the increase
573 in the EP-flux convergence and n_s^2 was discussed in Section 2. That is, wave tunneling or
574 wave reflection, separately or in combination, may invalidate the relationship between
575 the EP-flux and n_s^2 employed here [*Harnik* 2002]. In particular, whenever planetary
576 waves are propagating in the meridional plane they are likely undergoing horizontal
577 reflection because the wavelengths of the waves are longer than the width of the
578 waveguide (*Nili Harnik personal communication*). Thus because the EP-flux vectors

579 have a strong meridional component between ~10-15 km and 30°-50°N (Figures 1b and
580 2b), it is not surprising that the change in the propagation pattern of the EP-flux vectors is
581 not well described by the change in n_s^2 in this region. Yet a third possibility is that the
582 ZAO-induced changes in the stratospheric circulation have caused changes in the
583 troposphere that increase the generation of planetary wave activity. Indeed our results
584 show that ZAO affects the circulation of the troposphere (e.g., Figures 3 and 10a). Thus it
585 is possible that some of the increase in the EP-flux convergence in the UTLS is due to an
586 increase in planetary wave generation in the troposphere.

4. Summary and Conclusions

587 Using a middle atmosphere general circulation model, we have shown that
588 zonally asymmetric ozone (ZAO) alters the morphology of the PWG in three distinct
589 ways. First, the PWG contracts meridionally and expands vertically within the upper
590 stratosphere and lower mesosphere. Second, the magnitude of wave propagation
591 increases throughout the interior of the stratospheric waveguide between ~30°-75°N. And
592 third, the subtropical jet shifts equatorward. In combination, the changes in the shape and
593 strength of the PWG are associated with increased deceleration of the zonal-mean
594 westerly flow, resulting in a weaker and warmer stratospheric polar vortex. These
595 changes correlate well with the increased incidence of SSW's in the presence of ZAO
596 reported by *McCormack et al.* [2011].

597 Changes in the PWG have important implications for modeling SSWs, variations
598 in stratospheric dynamics associated with the 11-year solar cycle, and the Northern
599 Hemisphere annular mode (NAM). For example, *Charlton et al.* [2007] investigated the
600 ability of a series of GCMs – which did not consider the effects of ZAO on the PWG – to

601 generate an accurate number of SSWs. The results showed that most GCMs failed to
602 produce enough SSWs when compared to observations. In the current GCM study –
603 where we explicitly consider the effects of ZAO on the PWG – the model runs with ZAO
604 had a noticeably larger EP-flux emanating from the UTLS and produced a larger number
605 of SSWs compared to similar runs without ZAO. This increase in the EP-flux correlates
606 well with the increase in n_s^2 in the lower stratosphere, indicating that changes in the PWG
607 associated with ZAO may play an important role in modulating the flux of wave activity
608 entering the stratosphere from the troposphere, which is known to drive SSWs.

609 SSWs have also been correlated with a northward shift of tropical easterlies and
610 the zero wind line within the upper stratosphere and lower mesosphere [*Gray, 2003;*
611 *Vineeth et al., 2010*]. *Gray et al.* [2003] hypothesized that because vertically propagating
612 planetary waves have vertical wavelengths comparable to the distance between the
613 tropopause and the upper stratosphere during mid- to late-winter, it is possible that shifts
614 of the zero wind line in the upper stratosphere help guide waves poleward in much the
615 same manner as the traditional Holton-Tan mechanism in the lower stratosphere.
616 Although our experiments were not designed to test *Gray et al.*'s hypothesis, it is
617 nonetheless interesting to note the correlation between the northward shift in the zero
618 wind line and the increase in frequency of SSWs in our model runs that include ZAO.

619 In addition to SSWs, two aspects of the PWG discussed in this study – the width
620 and strength – may provide a means for ZAO to communicate and amplify the 11-year
621 solar cycle signal. The relationship between the width of the PWG and solar-modulated
622 ZAO has been shown by *Cordero and Nathan* [2005] to be an important pathway for
623 communicating the solar signal to the quasi-biennial oscillation (see their Figure 1).

624 Because our results show that ZAO plays a role in modulating the upper stratospheric
625 tropical easterlies, it is therefore likely that in a similar manner to the *Cordero and*
626 *Nathan* solar- quasi-biennial oscillation mechanism, ZAO may also play a role in
627 modulating the semi-annual oscillation in the tropical upper stratosphere. Because the
628 semi-annual oscillation plays a dominant role in the location and timing of shifts in the
629 upper stratospheric zero wind line, modulation of the semi-annual oscillation by ZAO
630 may provide an important pathway for solar modulation of the width of the PWG. Indeed,
631 this is a topic that deserves further attention given the parallel timing of the peak in wind
632 modulation from ZAO in our results and the robust solar signal observed during mid- to
633 late-winter in the tropical upper stratosphere [e.g., *Labitzke and van Loon*, 1988; *Naito*
634 *and Hirota*, 1997]. In addition to solar modulation of the width of the waveguide, ZAO
635 also provides a way to change the strength of wave propagation within the waveguide
636 itself. This scenario is supported by work demonstrating the link between the 11-year
637 solar cycle and changes in wave propagation and planetary wave drag in the extratropical
638 stratosphere [*Nathan et al.*, 2011; *Gabriel et al.*, 2011].

639 Finally, we note that the analysis in this paper has examined the effects of ZAO
640 from a “bottom-up” perspective. From this perspective, ZAO enhances the amount of
641 planetary wave activity that is refracted into the interior of the stratosphere from the
642 troposphere below. This phenomenon can be understood as a positive feedback cycle
643 where increases in the EP-flux convergence cause wind changes that increase n_s^2 within
644 the PWG; the increase in n_s^2 within the PWG in turn leads to further increases in the
645 vertical propagation of planetary waves with subsequent increases in the EP-flux
646 convergence. However, changes in the upward flux of planetary wave activity and

647 consequent variations in local wave-mean flow interaction in the stratosphere can also
648 drive downward propagating zonal-mean wind anomalies [*Plumb and Semeniuk, 2003*], a
649 “top-down” effect. Such downward propagating wind anomalies have been shown to be
650 important for stratosphere-troposphere communication [*Kodera and Kuroda, 2000*;
651 *Christiansen, 2001*; *Polvani and Waugh, 2004*; *Perlwitz and Harnik, 2004*] and NAM
652 variability [e.g. *Baldwin and Dunkerton, 1999*; *Limpasuvan and Hartmann, 2000*]. The
653 model simulations examined in this paper provide evidence that *ZAO affects both the*
654 *downward propagation of wind anomalies and the phase of the NAM*. The downward
655 propagation of the wind anomalies is seen in the space-time evolution of the ZAO-
656 induced wind anomalies depicted in Figure 3 and in *McCormack et al. [2011]* (see their
657 Figures 4a-d). The effect of ZAO-heating on the phase of the NAM is seen in the
658 equatorward shift in the subtropical jet and a weakened polar vortex (compare Figure 3
659 and Figure 7), which are both common features of the low index phase of the NAM. The
660 equatorward shift in the subtropical jet shown in our results is consistent with the work of
661 *Brand et al. [2008]* who found that including ZAO produces a shift in the NAM towards
662 its low index phase; this indicates that the relationship between ZAO and shifts in the
663 phase of the NAM is likely a robust result. We are currently investigating the effects of
664 ZAO on downward signal propagation and annular mode variability.

810

811 **Figure 1.** Three-month average (DJF) ZMO3 ensemble mean (a) zonal-mean wind and (b)812 n_s^2 with EP-flux vectors. In (a) the thick black line denotes the zero-wind line. In (b) the813 contours denote n_s^2 , which has been non-dimensionalized with a^2 (contour interval is 4).

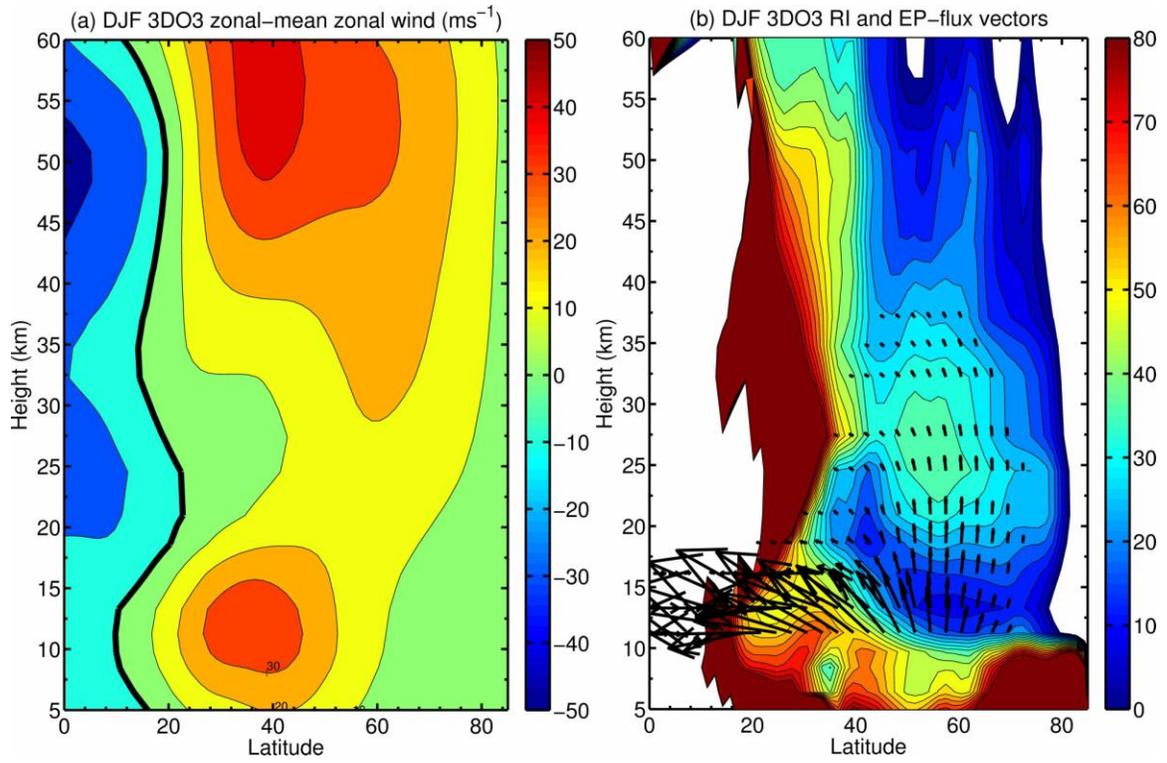

814 The EP-flux vectors (arrows) are plotted only in regions where the EP-flux divergence is

815 less than $\sim -25 \times 10^6 \text{ kg s}^{-2}$ (this threshold eliminates visually distracting vectors that are

816 inconsequential to the physics). The scaling of the EP-flux vectors is discussed in Section

817 2.

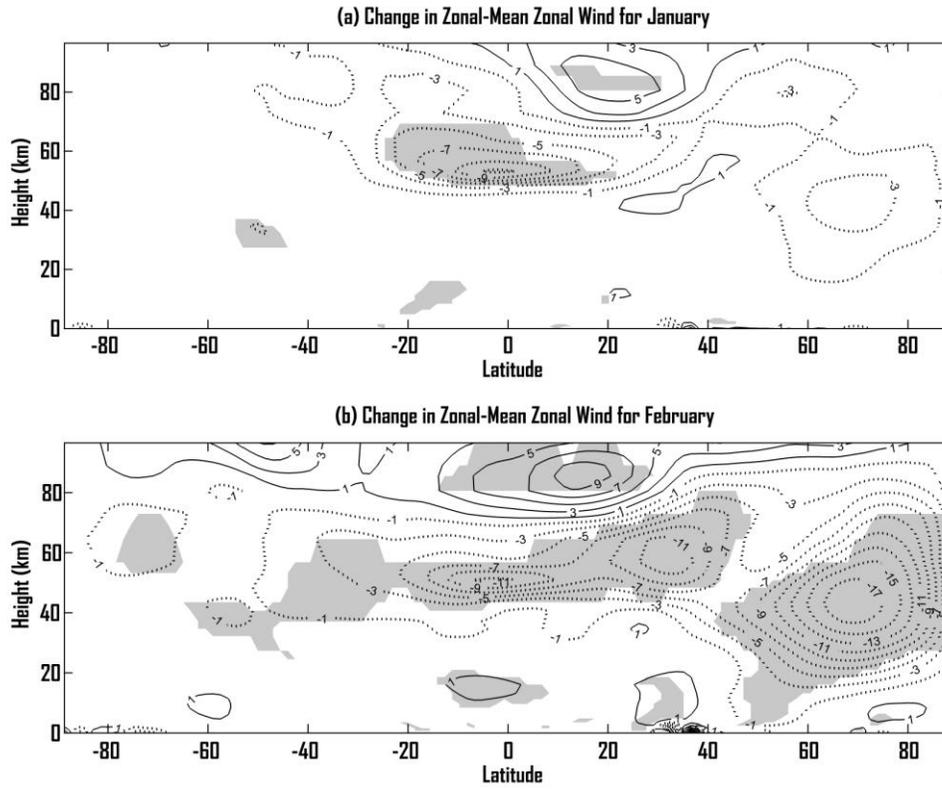

818

819

820 **Figure 2.** As in Figure 1, but for the 3DO3 ensemble mean.

821

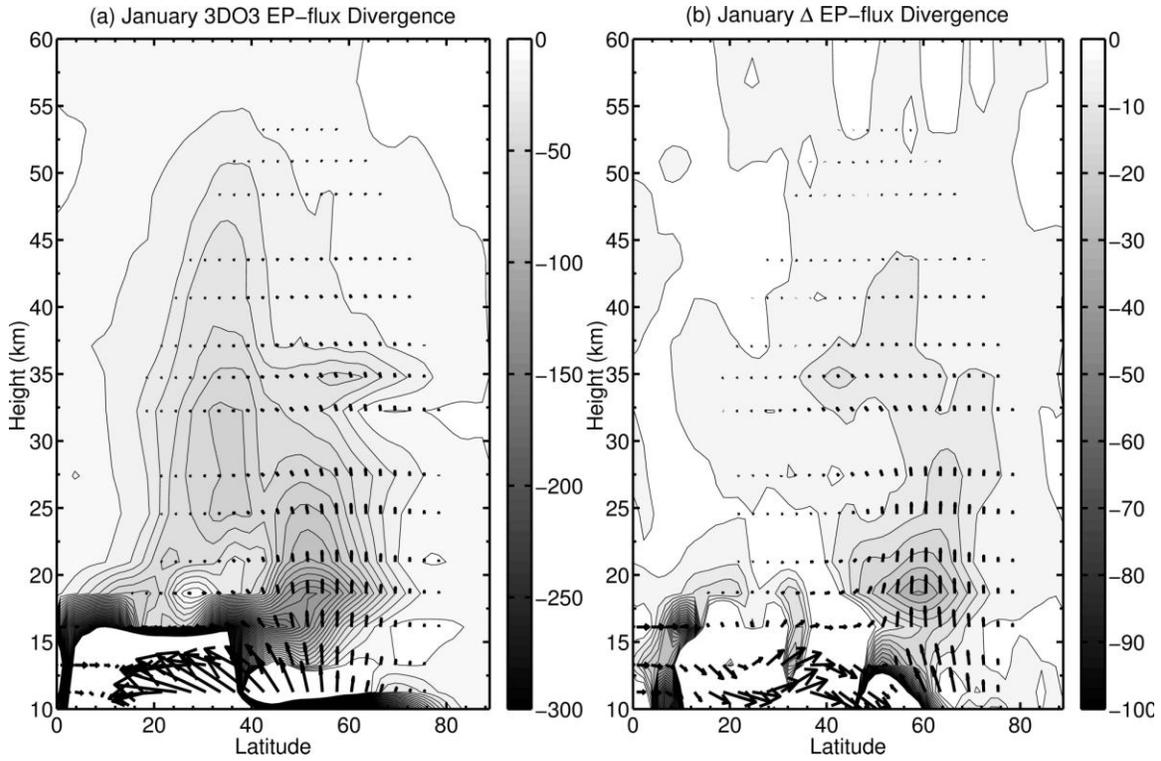

822

823 **Figure 3.** Monthly average zonal-mean wind difference ($\Delta U = 3D03$ minus $ZMO3$) for:824 (a) January and (b) February. Contours intervals are in units of ms^{-1} . Statistically

825 significant wind changes at the 95% confidence level are shaded in gray.

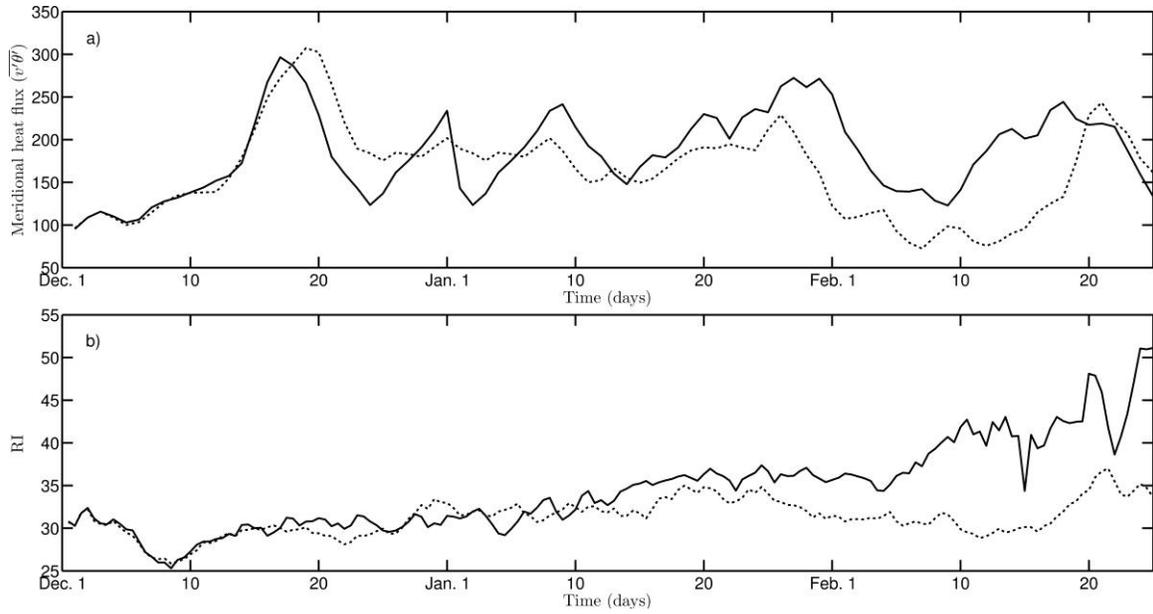

826

827

828 **Figure 4.** January ensemble mean for (a) 3DO3 EP-flux convergence with EP-flux vectors
 829 and (b) the difference (3DO3 minus ZMO3) in the EP-flux convergence and EP-flux
 830 vectors. In (a), the white region between 0°- 40°N latitude and below ~15 km represents
 831 EP-flux convergence that is greater than the 0 to -300 scale used for plotting. In both
 832 plots the units are $1 \times 10^6 \text{ kg s}^{-2}$ and the contour interval is $5 \times 10^6 \text{ kg s}^{-2}$. As in Figures 1
 833 and 2, the EP-flux vectors in (b) are only plotted in regions where the EP-flux divergence
 834 is less than the threshold $\sim -25 \times 10^6 \text{ kg s}^{-2}$. The scaling of the EP-flux vectors is discussed
 835 in Section 2; the magnitude of the vectors in (a) and (b) are consistent with the EP-flux
 836 convergence scale shown alongside each plot.

837

838

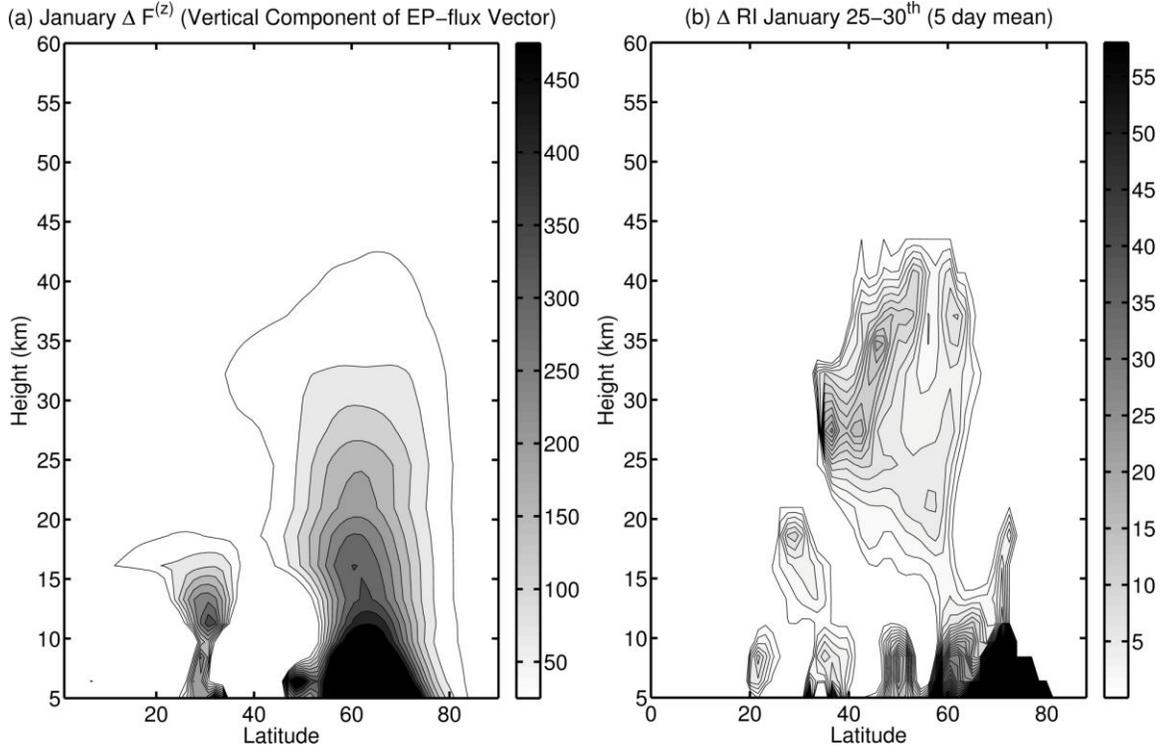

839 **Figure 5.** Time series of ensemble mean, area-weighted average (50° - 75° N) at ~ 27 km for
 840 the (a) meridional heat flux and (b) n_s^2 between December-February for 3DO3 (solid lines)

841 and ZMO3 (dotted lines). The heat flux is in units of K ms^{-1} , while n_s^2 has been non-

842 dimensionalized by a^2 .

843

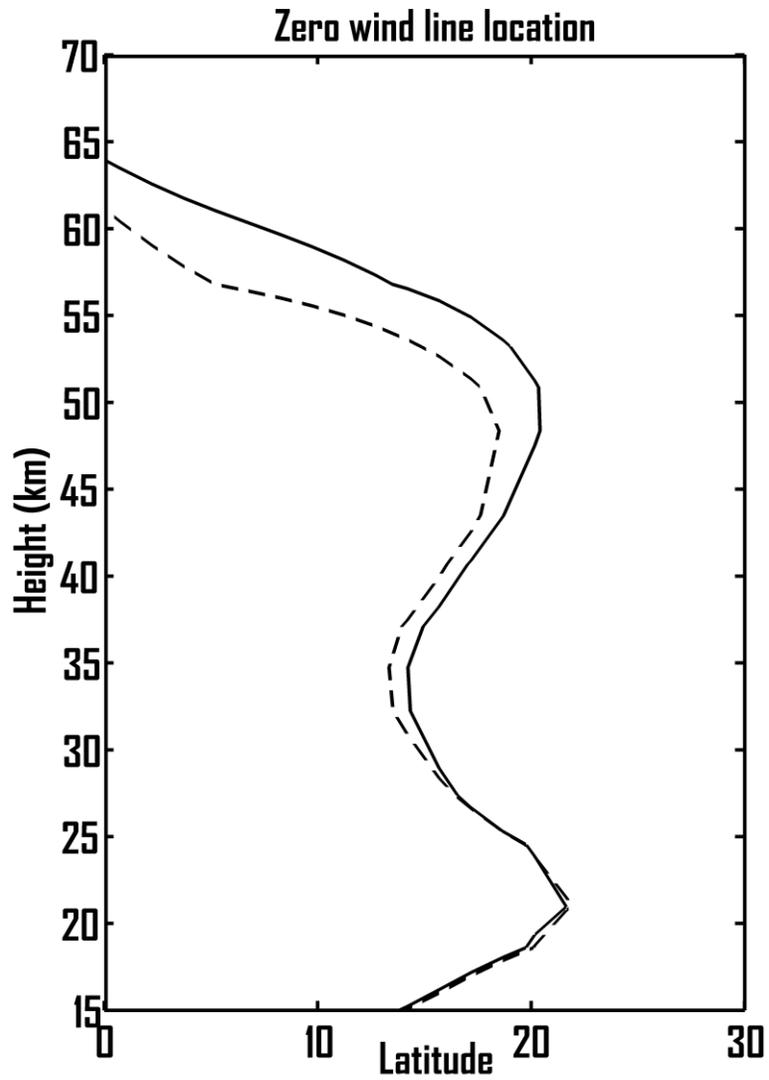

844

845

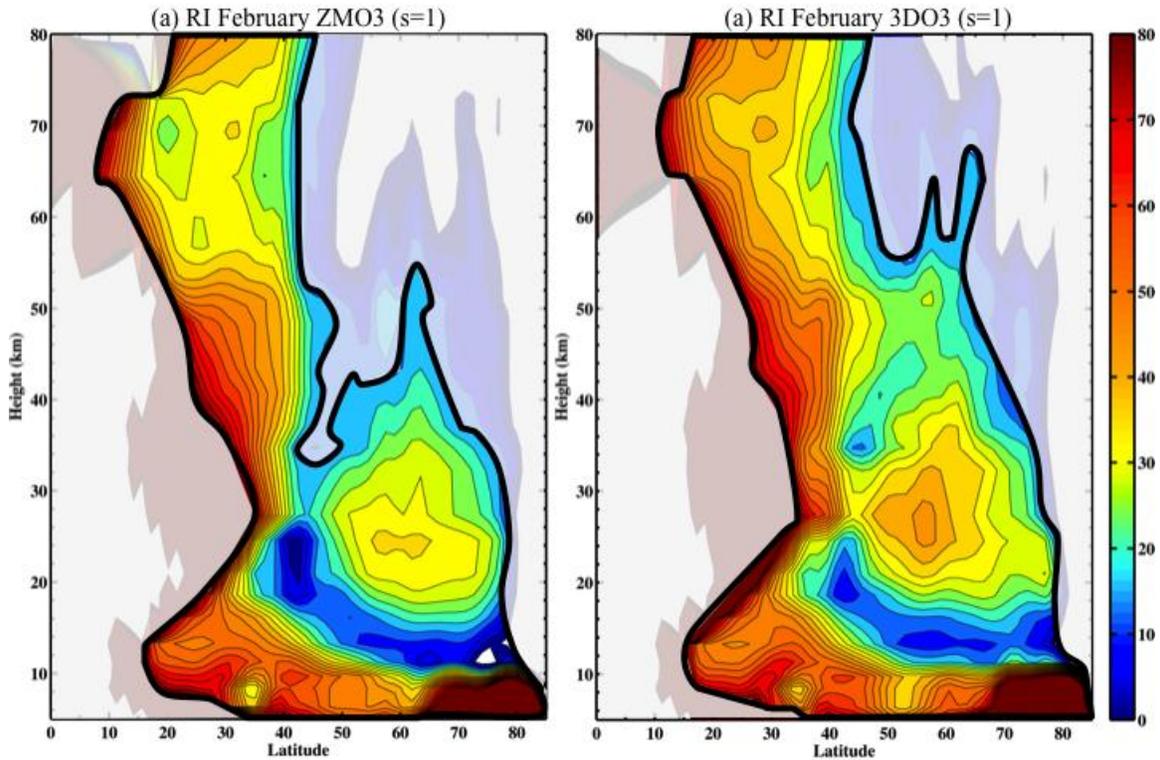

846 **Figure 6.** (a) Contours of the difference (3DO3 minus ZMO3) in ensemble mean vertical
 847 component of the EP-flux vector for January. Units are $1 \times 10^{-9} \text{ kg} \cdot \text{m} \text{ s}^{-2}$ and the contour
 848 interval is $5 \times 10^{-8} \text{ kg} \cdot \text{m} \text{ s}^{-2}$. (b) Difference in the late January n_s^2 for the period between
 849 January 25-31. For visual clarity, the n_s^2 data was filtered so that the n_s^2 is plotted only in
 850 regions where the EP-flux divergence is less than the same minimum threshold value ($\sim -$
 851 $25 \times 10^6 \text{ kg} \text{ s}^{-2}$) used when plotting the EP-flux vectors in Figures 1b and 2b; see Figure 4a
 852 for EP-flux divergence scale.

853

854

855 **Figure 7.** Location of February Northern Hemisphere zero wind line for 3DO3 (solid
856 line) and ZMO3 (dashed line).

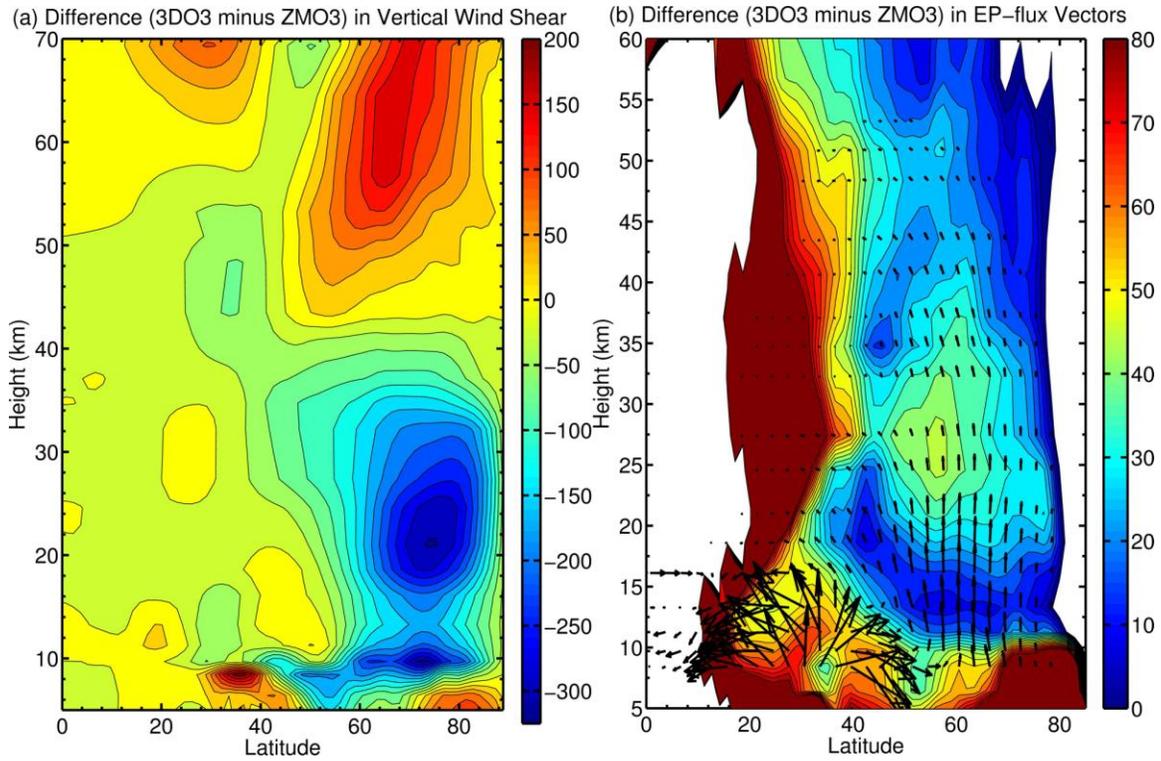

857

858 **Figure 8.** Monthly averaged n_s^2 for February: (a) ZMO3 for planetary wave $s=1$; and (b)859 3DO3 for planetary wave $s=1$. The n_s^2 scale extends from red to blue, which corresponds860 with large to small n_s^2 , respectively; regions where planetary waves are evanescent861 ($n_s^2 < 0$) are denoted by white space. We indicate the shape of the PWG by choosing a862 specific, though arbitrary, contour for n_s^2 . Irrespective of the choice of the contour,

863 however, the shape of the PWG remains qualitatively unchanged. The solid black line

864 that outlines the PWG traces the 15 and 65 n_s^2 contours on the poleward and equatorward865 side of the PWG, respectively. In all plots, n_s^2 has been non-dimensionalized by a^2 ; the

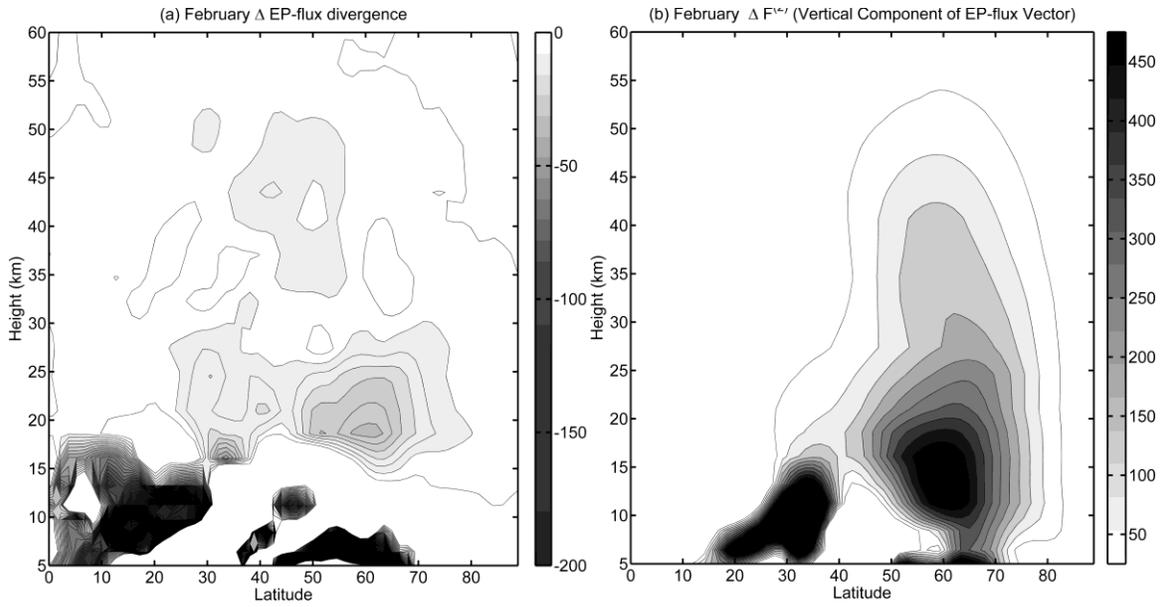

866 contour interval is 4.

867

868 **Figure 9.** (a) The difference (3DO3 minus ZMO3) in the ensemble-mean vertical wind
 869 shear for February; the contour interval is in units of m s^{-2} . (b) The difference (3DO3
 870 minus ZMO3) in the EP-flux vectors for February; the ensemble mean February 3DO3
 871 n_s^2 is plotted in the background for reference. As in Figures 1 and 2, the EP-flux vectors
 872 in (b) were filtered so that vectors are only plotted in regions where the EP-flux
 873 divergence is less than $\sim -25 \times 10^6 \text{ kg s}^{-2}$. The scaling of the EP-flux vectors is discussed
 874 in Section 2.

875

876

877 **Figure 10.** (a) February ensemble-mean difference (3DO3 minus ZMO3) in the EP-flux
 878 convergence. The units are $1 \times 10^6 \text{ kg s}^{-2}$ and the contour interval is $5 \times 10^6 \text{ kg s}^{-2}$. (b)
 879 Contours of the difference (3DO3 minus ZMO3) in ensemble mean vertical component of
 880 the EP-flux vector for February. The units are $1 \times 10^{-9} \text{ kg} \cdot \text{m s}^{-2}$ and the contour interval is
 881 $5 \times 10^{-8} \text{ kg} \cdot \text{m s}^{-2}$.
