

**₁ Satellite Detection of Orographic Gravity-Wave
₂ Activity in the Winter Subtropical Stratosphere over
₃ Australia and Africa**

4 Orographic gravity-wave (OGW) parameterizations in models produce waves
5 over subtropical mountain ranges in Australia and Africa that propagate into
6 the stratosphere during austral winter and deposit momentum, affecting weather
7 and climate. Satellite sensors have measured stratospheric GWs for over a
8 decade, yet find no evidence of these waves. So are parameterizations fail-
9 ing here? Here we argue that the short wavelengths of subtropical OGWs
10 place them near or below the detection limits of satellite sensors. To test
11 this hypothesis, we reanalyze nine years of stratospheric radiances from the
12 Atmospheric Infrared Sounder (AIRS) on NASA's Aqua satellite during aus-
13 tral winter, applying new averaging techniques to maximize signal-to-noise
14 and improve thresholds for OGW detection. Deep climatological enhance-
15 ments in stratospheric OGW variance over specific mountain ranges in Aus-
16 tralia and southern Africa are revealed for the first time, which exhibit tem-
17 poral and vertical variations consistent with predicted OGW responses to
18 varying background winds.

1. Introduction

19 High-resolution high-precision stratospheric radiances from limb and nadir satellite sen-
20 sors can resolve temperature perturbations produced by long-wavelength gravity waves
21 (GWs), providing insights into the global distribution of stratospheric GW activity [*Wu et*
22 *al.*, 2006]. In austral winter, climatologies reveal a band of enhanced variance at $\sim 40\text{--}70^\circ\text{S}$,
23 punctuated by localized “hot spots” due to deep stratospheric propagation of orographic
24 gravity waves (OGWs) from major mountain ranges, such as the southern Andes, south-
25 ern Alps, and coastal Antarctic mountain ranges [e.g., *Eckermann and Preusse*, 1999;
26 *McLandress et al.*, 2000; *Wu*, 2004; *Jiang et al.*, 2005; *Wu and Eckermann*, 2008; *Alexan-*
27 *der et al.*, 2008; *Yan et al.*, 2010; *Gong et al.*, 2012], as well as from small mountainous
28 islands scattered along the Southern Ocean [*Wu et al.*, 2006; *Alexander et al.*, 2009].

29 Conversely, in the southern winter subtropics ($25^\circ\text{--}40^\circ\text{S}$), satellite sensors detect few
30 deep stratospheric orographic gravity waves (SOGWs), despite the presence of greater
31 and more significant orography at these latitudes. While satellite sensors regularly detect
32 SOGWs over the subtropical Andes [*Jiang et al.*, 2002; *Wu*, 2004], significant subtropical
33 orography in Africa and mainland Australia yields no clear SOGW signatures. Why?

34 The simplest explanation is that there are no waves to observe. On moving equator-
35 ward, prevailing mid-latitude westerlies near the surface and throughout the stratosphere
36 weaken significantly and eventually reverse, reducing surface forcing and inhibiting SOGW
37 penetration through critical-level filtering and wave breaking in the lower stratosphere.
38 Yet deep mountain-wave hindcasting by *Jiang et al.* [2005] has shown that these effects
39 alone do not prevent deep climatological SOGW signatures from occurring over subtropi-

40 cal Australian and African orography in austral winter. Parameterizations in weather and
41 climate models also predict significant deposition of SOGW momentum in the southern
42 winter subtropics [e.g., *Scinocca and McFarlane, 2000*].

43 While this discrepancy could of course point to model shortcomings, another possibility
44 is an inability of satellite sensors to detect these SOGWs. Subtropical Australian and
45 African mountain ranges are lower and narrower than the subtropical Andes, forcing
46 OGWs with shorter horizontal wavelengths λ_h and smaller amplitudes. OGW vertical
47 wavelengths λ_z are proportional to local wind speeds U , and both reduce considerably
48 on moving from midlatitudes to subtropics [*Jiang et al., 2002*]. The anticipated small
49 amplitude and short wavelengths of these waves means that their signals in nadir and
50 limb radiances will be weak, and possibly too weak to exceed channel noise floors.

51 Here we undertake a systematic reanalysis of GW perturbations in stratospheric thermal
52 radiances from the Atmospheric Infrared Sounder (AIRS) on NASA's polar-orbiting Aqua
53 satellite, employing a range of averaging procedures to yield radiance scenes with reduced
54 background noise levels. The objective is to see whether statistically significant signatures
55 of subtropical SOGWs, previously buried within the noise, emerge over Australia and
56 Africa in austral winter.

2. Noise-Reduced Gravity-Wave Signals from AIRS Radiances

57 AIRS is a passive infrared sensor that scans the atmosphere perpendicular to the satel-
58 lite track in a repeating series of 90 measurements distributed symmetrically about the
59 nadir. Areas of individual measurement footprints range from $\sim 13 \times 13 \text{ km}^2$ at nadir to
60 $\sim 31 \times 21 \text{ km}^2$ at the far off-nadir. As Aqua orbits, AIRS sweeps out pole-to-pole measure-

61 ment swaths ~ 1650 km wide, accumulating radiances from over 2300 channels, most of
62 which are tropospheric but many of which peak in the stratosphere. While the contri-
63 bution functions for these radiances are vertically broad, the high radiometric precision
64 and low noise levels of individual channels, coupled with small measurement footprints,
65 allow temperature perturbations of deep (long λ_z) GWs to be resolved as horizontal two-
66 dimensional wave structure in the pushbroom radiance imagery from many stratospheric
67 channels.

68 From 100-20 hPa there are redundant AIRS thermal channels that peak at nearly the
69 same altitude with very similar vertical weighting functions. Following *Eckermann et al.*
70 [2009] and *Gong et al.* [2012], we averaged version 5 radiances from 50 AIRS channels to
71 produce a mean radiance product at 12 pressure levels from 100-2 hPa [see Table A2 of
72 *Gong et al.*, 2012]. At the lowest levels of 100 hPa, 80 hPa and 60 hPa, where we most
73 require reduced noise for better GW detection near the source, the product was derived
74 by averaging radiances from 6, 14 and 9 individual AIRS channels, respectively.

75 Occasionally these data revealed outbreaks of anomalous radiance at specific scan angles,
76 often prior to extended periods of missing data. This striping prevents a clean isolation of
77 small-scale GW perturbations and contaminates variance maps, so daily radiance maps
78 from 2003-2011 were carefully screened to identify and remove errant granules.

79 GW perturbations were isolated by fitting and removing large-scale radiance structure,
80 as follows. Swath radiances were first smoothed along track using a 33-point running
81 average (~ 660 km), then each scan was fitted cross track using a sixth-order polynomial,
82 to capture both geophysical cross-track gradients as well as systematic scan-angle trends

83 due to the limb effect. These smoothed fields were subjected to a final 15-point along-
84 track running average, then subtracted from the original radiances to isolate small-scale
85 perturbation structure. The radiance perturbation maps were smoothed using a 3x3 point
86 running average to reduce random noise levels still further. Perturbation variances at each
87 level were computed and stored daily on a global $0.5^\circ \times 1^\circ$ longitude-latitude grid.

3. Subtropical SOGWs over Australia

88 Figure 1a plots topographic elevations over southern Australia. Remaining panels show
89 root-mean-square (rms) GW-induced brightness temperature perturbations, \hat{T}_{rms} , at al-
90 titudes from 100 hPa up to 2 hPa, averaged throughout austral winter (June-August) for
91 the years 2003-2011. This nine-year climatology reveals for the first time clear “hot spots”
92 of SOGW activity in the lower stratosphere from 100-60 hPa (Figure 1b–1d) associated
93 with major Australian mountain ranges labeled in Figure 1a: the Great Dividing Range
94 on the east coast, and the Flinders Ranges in southern Australia to the north of Ade-
95 laide. The improved signal-to-noise levels even reveal a weak but distinct SOGW signal
96 on the southwest coast associated with the Darling Ranges, a comparatively low mountain
97 escarpment running along the west Australian coast near Perth. A notable feature of all
98 three SOGW-generating mountain ranges is their two-dimensional structure and north-
99 south alignment, which, like the Andes, is favorable for strong surface OGW forcing and
100 deep stratospheric propagation within a prevailing westerly winter flow at all altitudes.
101 A fourth (midlatitude) SOGW enhancement is evident at 100–60 hPa over Tasmania.

102 On progressing deeper into the stratosphere, \hat{T}_{rms} maps develop a band of elevated
103 values poleward of 40°S . This results from intensifying stratospheric westerlies that refract

104 nonorographic GWs at these latitudes to long λ_z values, making them easier for AIRS
 105 to resolve and producing larger radiance signals. Nonetheless, the largest \hat{T}_{rms} values
 106 at these latitudes are still associated with SOGWs from Tasmania, as has been noted
 107 in some earlier studies [*Wu, 2004; Jiang et al., 2005*]. Despite the dominance of these
 108 midlatitude GW radiance signals at upper levels, the \hat{T}_{rms} maps continue to show local
 109 SOGW maxima over the Great Dividing Range, Flinders Ranges, and even (weakly) over
 110 the Darling Range all the way up to 2 hPa (Figure 1e), consistent with deep propagation
 111 of these subtropical SOGWs.

112 Boxes in Figure 2a demark these four regions of SOGW activity, within which daily
 113 \hat{T}_{rms} values are computed. Figure 3 plots resulting daily time series of \hat{T}_{rms} at three
 114 different altitudes. In the lower stratosphere at ~ 80 hPa (bottom row of Figure 3),
 115 the time series reveal sporadic generation of waves throughout May-September, with a
 116 weak tendency for greater activity in winter. The largest values occur over the Great
 117 Dividing Range, consistent with Figure 1c. By contrast, \hat{T}_{rms} time series at 7 hPa and
 118 2 hPa reveal largest values over Tasmania, mostly confined to the austral winter months
 119 of June-August, whereas values over the three subtropical SOGW regions in mainland
 120 Australia are weaker and enhancements are restricted to June and July only.

121 To investigate the origins of this upper-level variability, Figures 2b and 2c show time
 122 series of zonal winds at 32°S and 43°S , respectively, over a limited range of Australian
 123 longitudes, depicted with broken gray curves in Figure 2a. These plots reveal stronger
 124 upper-level westerlies over Tasmania relative to mainland Australia, which refract Tasma-
 125 nian SOGWs to longer λ_z values. These longer Tasmanian SOGWs are easier for AIRS to

126 detect than shorter subtropical SOGWs over mainland Australia, explaining their larger
 127 radiance signals from ~ 20 – 2 hPa. By contrast, at ~ 80 hPa, where wind speeds are more
 128 comparable at both latitudes, Tasmanian SOGW signals no longer dominate,

129 Shaded regions in Figures 2b and 2c show times when and altitudes where mean zonal
 130 winds are less than $+5$ m s $^{-1}$. It is difficult for SOGWs to propagate through these shaded
 131 regions to higher altitudes, due to critical-level removal or significant dissipation of wave
 132 energy due to wave breaking. Figure 2b reveals only a two month window in June and July
 133 at 32° S where these weak or reversed winds are absent and provide a favorable propagation
 134 channel to upper altitudes, consistent with observations in Figure 3 showing upper-level
 135 \hat{T}_{rms} enhancements over mainland Australia confined to June and July. Figure 2c shows
 136 that at 43° S, this window expands into August, consistent with enhanced upper-level \hat{T}_{rms}
 137 values over Tasmania in Figures 3j and 3k from June through August.

4. Subtropical SOGWs over southern Africa

138 We have applied the same analysis to search for subtropical SOGW signals over southern
 139 regions of Africa. Like Australia, AIRS radiances from 100–60 hPa reveal isolated hot spots
 140 in Figures 4b–4d associated with SOGWs generated by local mountain ranges evident in
 141 Figure 4a: the Drakensberg Mountains and Cape Fold Belt in South Africa and the Huns
 142 and Karas Mountains in Namibia. As in the Australian sector, on progressing upwards
 143 the \hat{T}_{rms} maps acquire a belt of elevated values over the Southern Ocean. Nonetheless, the
 144 upper-level \hat{T}_{rms} maps still show local subtropical maxima over the land masses relative
 145 to ocean regions to the east and west. While not as clear as over mainland Australia,

146 these observations nevertheless show that these subtropical SOGWs over South Africa
147 and Namibia propagate deep into the upper stratosphere.

5. Summary

148 This study has resolved a discrepancy between models and observations by showing for
149 the first time that subtropical mountain ranges in Australia and Africa generate OGWs
150 that can be observed propagating deep into the stratosphere during austral winter. These
151 waves had previously evaded satellite detection due to their short wavelengths, which
152 place them at the resolution limits of limb and nadir sensors. Despite their small ob-
153 served radiance signals, this deep subtropical SOGW activity is dynamically important,
154 since parameterizations predict significant deposition of SOGW momentum in the south-
155 ern subtropical lower stratosphere during austral winter [*Scinocca and McFarlane, 2000*],
156 which in turn impacts large-scale weather and climate.

157 We found no clear SOGW signals equatorward of $\sim 25^\circ\text{S}$ over Australia or Africa in
158 austral winter. While even shorter SOGWs may exist here that continue to evade satellite
159 detection, at these lower latitudes zero-wind lines form at ~ 30 hPa over the Australian
160 and African sectors which likely absorb many SOGWs via critical-level interactions.

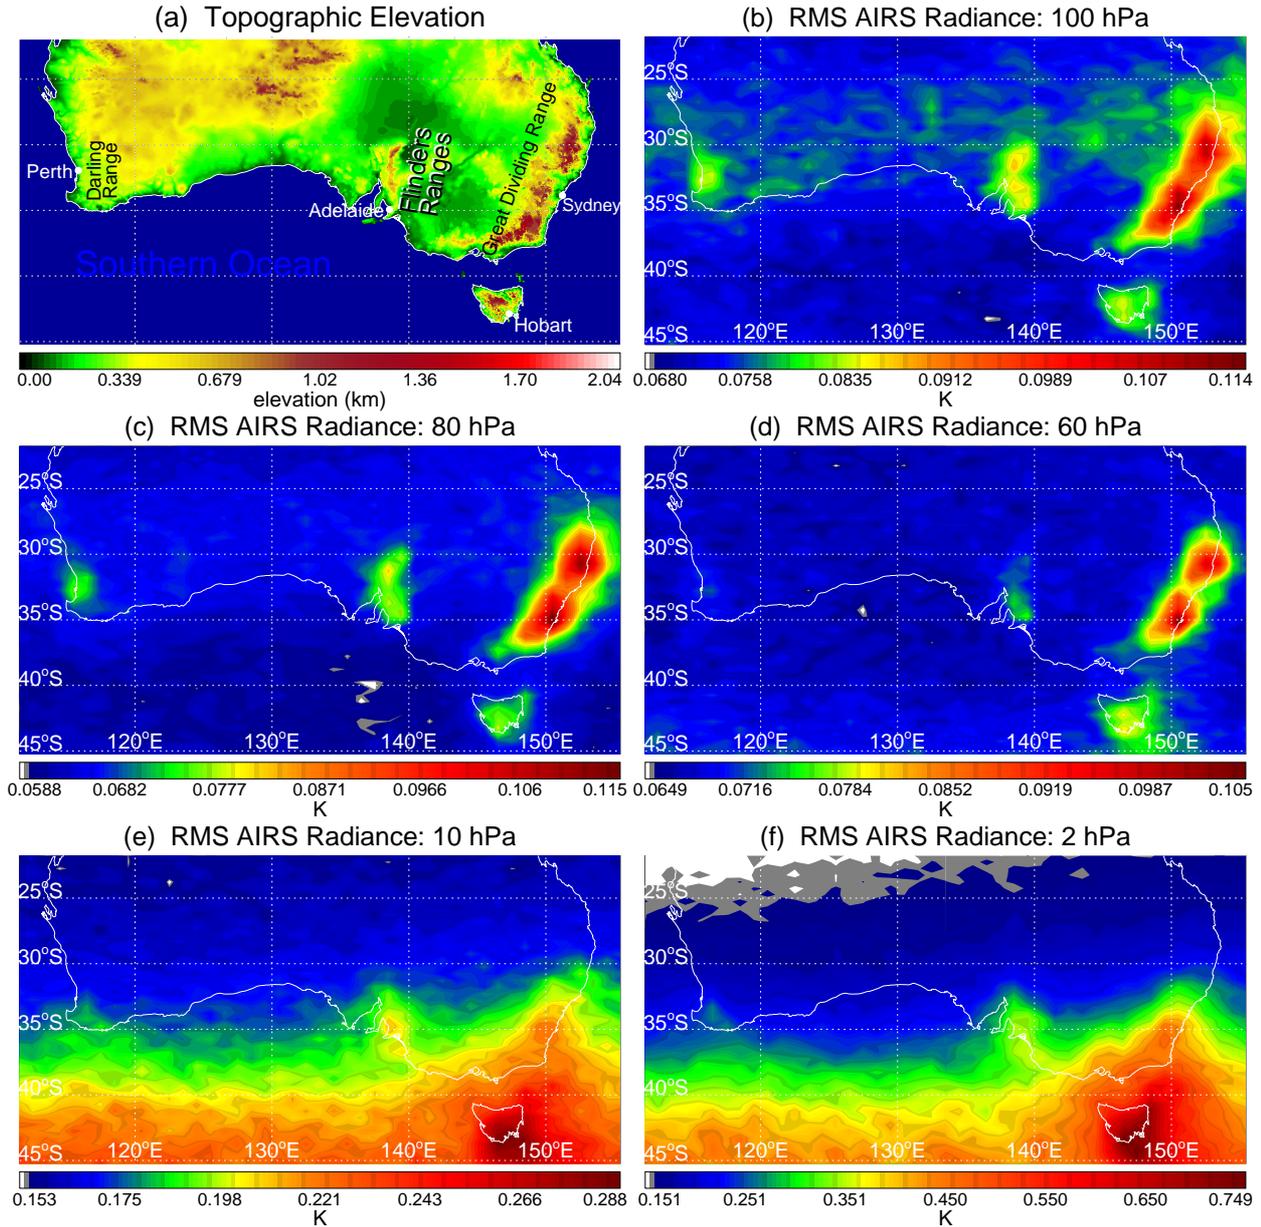

Figure 1. (a) Topographic elevations showing major mountain ranges over southern mainland Australia. Remaining panels show corresponding maps of rms SOGW-induced anomalies in AIRS brightness temperatures, \hat{T}_{rms} , averaged on a $0.5^\circ \times 1^\circ$ grid from June-August for the years 2003-2011, based on noise-reduced radiance imagery at (b) 100 hPa, (c) 80 hPa, (d) 60 hPa, (e) 10 hPa, and (f) 2 hPa.

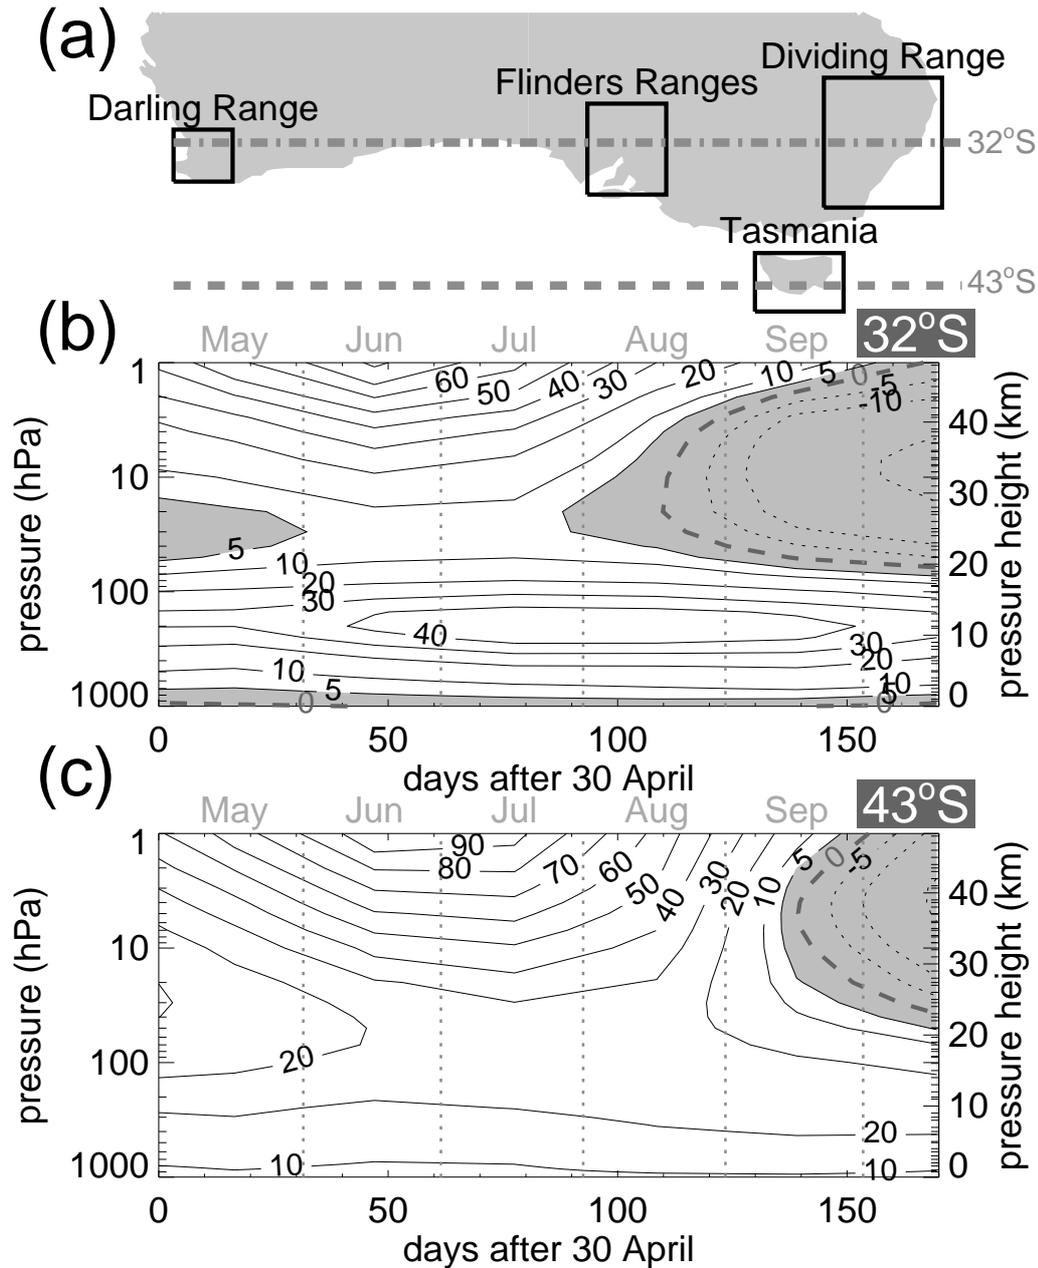

Figure 2. (a) Boxes show SOGW-active regions in Figure 1 that are used to compute \hat{T}_{rms} time series in Figure 3. Broken gray lines show longitudinal regions at a given latitude where reanalysis zonal winds of *Rienecker et al.* [2011] are averaged from 2003–2011 and plotted versus time and height at (b) 32°S and (c) 43°S. Contour labels are in m s^{-1} , solid (dotted) contours depict westerlies (easterlies). Shaded regions denote winds $\leq 5 \text{ m s}^{-1}$.

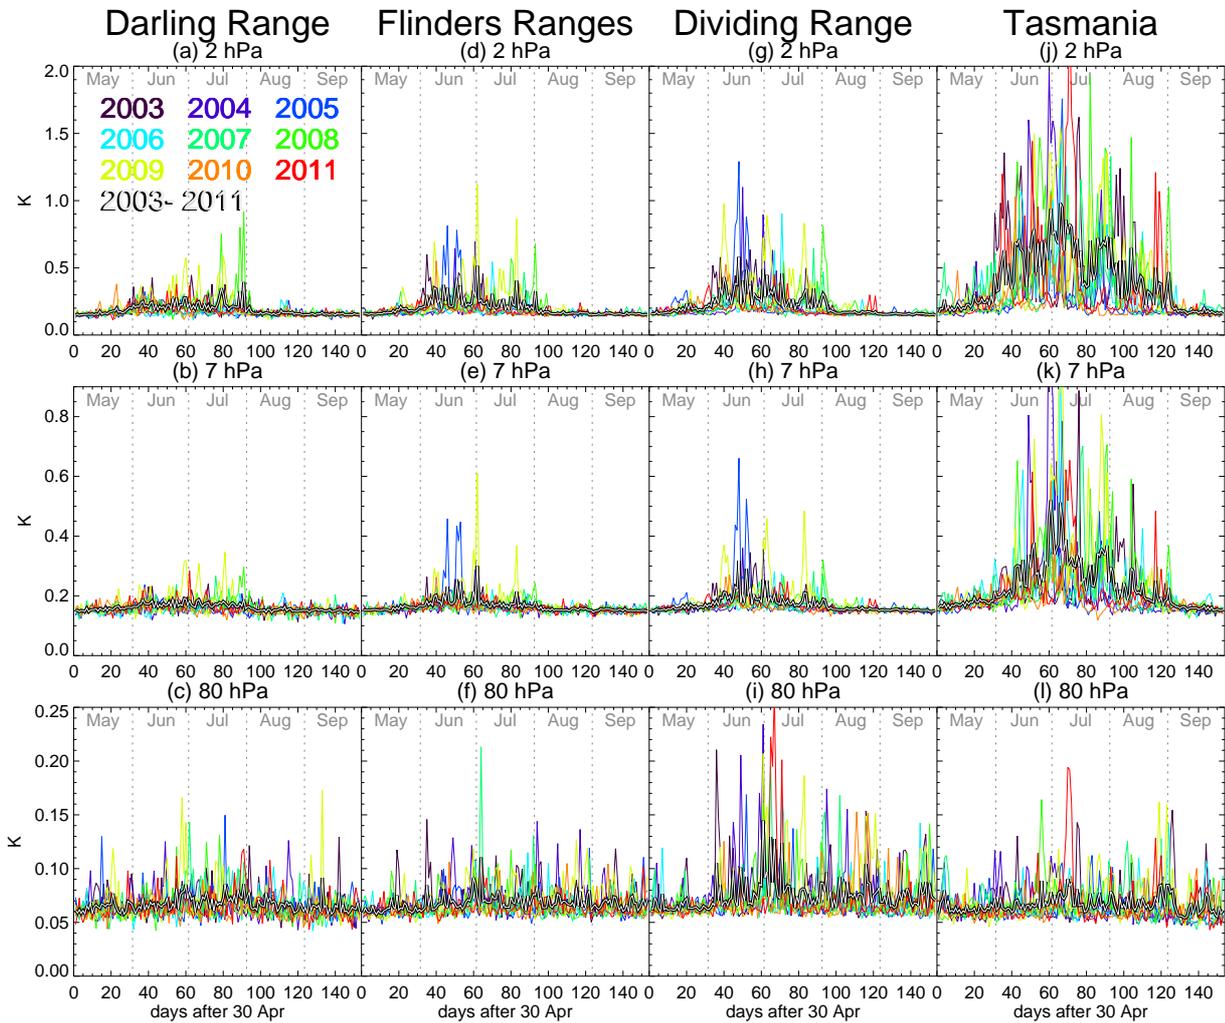

Figure 3. Daily time series of \hat{T}_{rms} at 80 hPa (bottom row), 7 hPa (middle row) and 2 hPa (top row) from May-September within the four Australian SOGW regions identified in Figure 2a. Colored curves show time series for individual years (see color key in panel a), while the thick white-on-black curves show the nine-year mean.

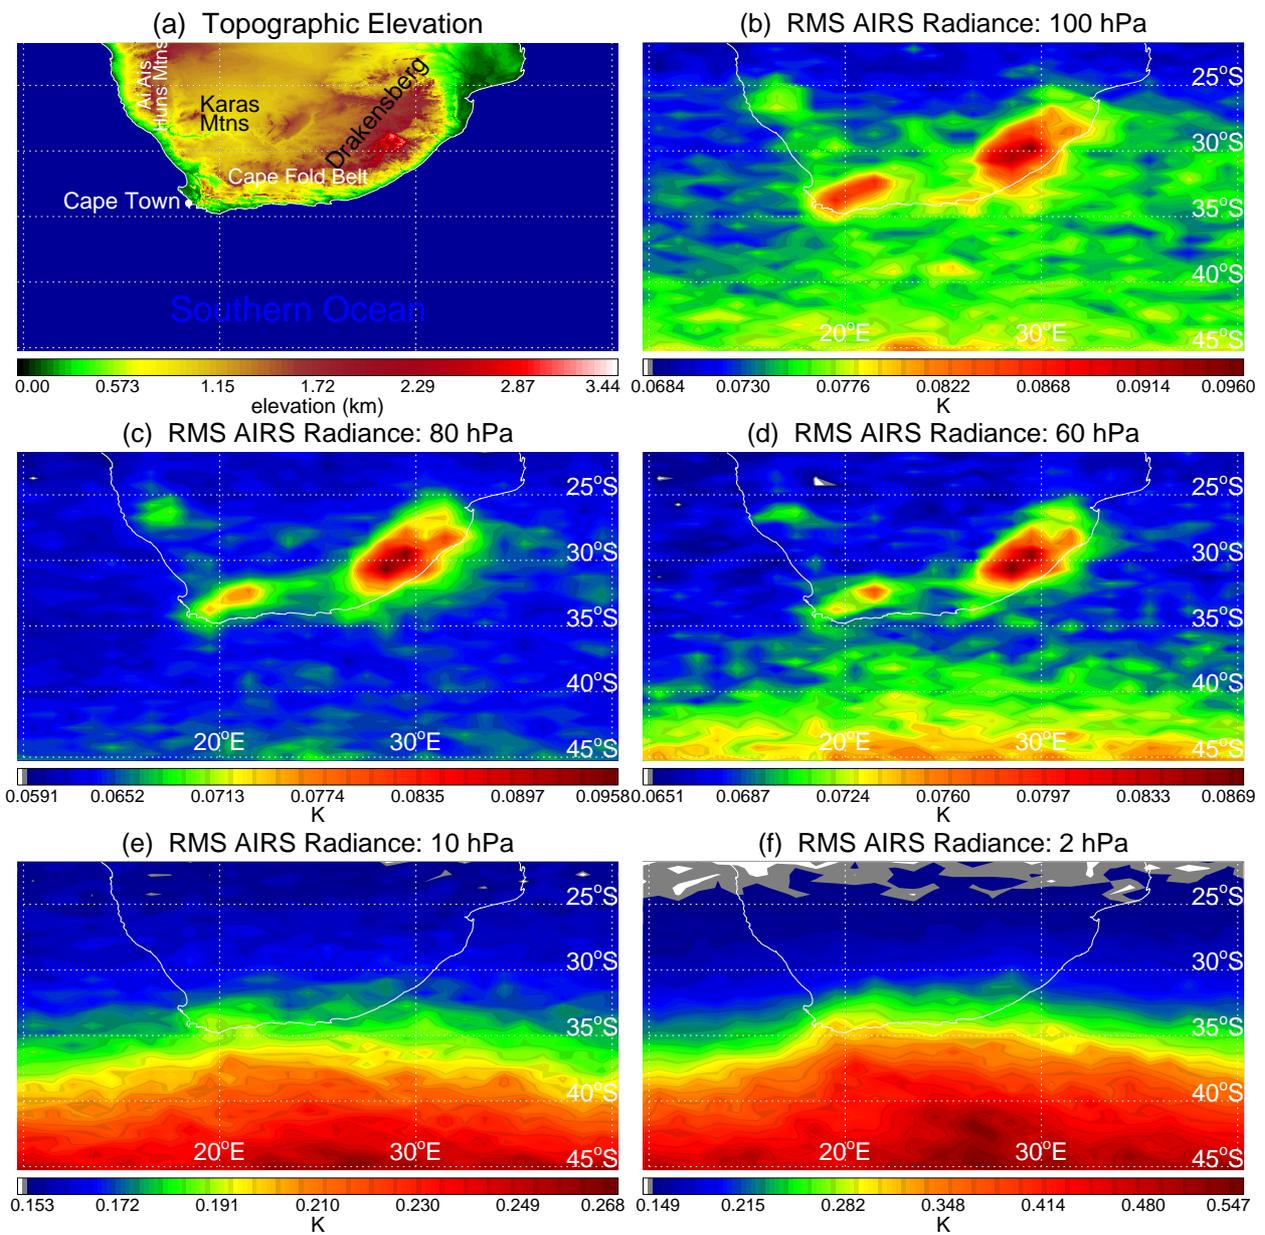

Figure 4. As for Figure 1, but focusing on the southern Africa region.
